## Chapter 15 Detector and physics performance

The overall performance of the CEPC reference detector is established using a detailed GEANT4 model [1] and full reconstruction of the simulated events. Most of the sub-detectors have been designed with a detailed engineering considerations, including mechanical support structures, electronics, cabling, as well as dead material and cracks. The material budget associated with the support structures and services is based on the best current estimates from the detector R&D groups. Using full simulation and a realistic reconstruction helps ensure that the performance is as realistic as possible and takes into account the detailed knowledge of detector mechanics, dead areas, and non-perfect response. All events are reconstructed using a sophisticated reconstruction chain, with a Kalman-filter based track reconstruction and the CyberPFA particle flow algorithm. A description of the detector parameters and the reconstruction software can be found in the Chapter ??.

In this chapter, the performance of physics objects from the reference detector is discussed in Section 15.1. Then, a series of different physics studies done using full Monte Carlo at different center of mass energies from 91 to 360 GeV are presented in Section 15.2. These analyses have not been selected to demonstrate the physics reach at CEPC, but rather to stress the detector and its performance. Section 15.3 outlines the strategies for measuring absolute luminosity, the use of resonant depolarization to measure the  $Z$  and  $W$  masses with high precision, methods for the calibration and alignment for CEPC sub detectors, and the primary areas where detector configuration optimizations and technology decisions could be further explored. Section 15.4 provides a brief summary of the key performance metrics achieved with the reference detector.

### 15.1 Detector performance

To assess the efficacy of the reference detector and the associated reconstruction software, an in-depth examination of the performance metrics for tracking, Particle Identification (PID), vertexing, and particle flow algorithms has been conducted.

#### 15.1.1 Tracking

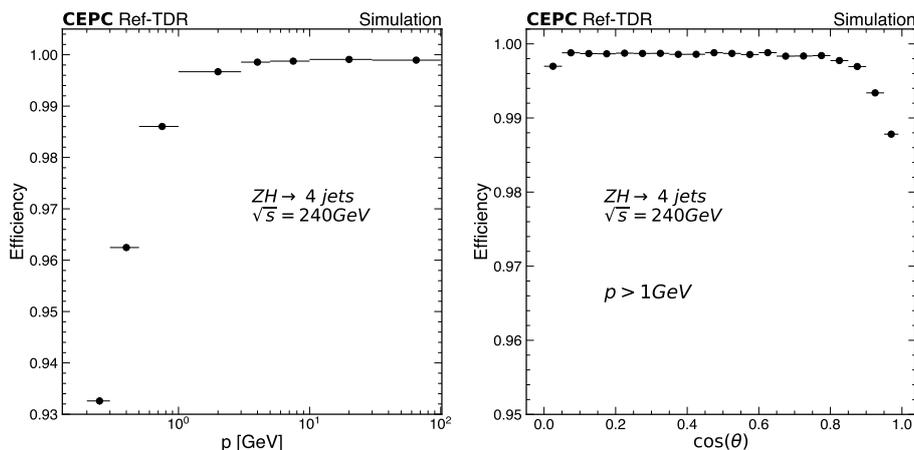

The tracking system of the reference detector is designed around three subsystems capable of standalone tracking: the vertex detector (VTX), the inner silicon tracker (ITK) and the time projection chamber (TPC). These are augmented by an auxiliary tracking system, the outer tracker (OTK), which utilizes the AC-LGAD and provides both additional high-resolution measurement points and time of flight information. The TPC provides full

74 coverage down to  $\theta \approx 32^\circ$ , beyond which the number of measurement points decreases.  
 75 The final measurement point provided by the TPC is at  $\theta \approx 11.7^\circ$ . The central inner  
 76 tracking system, comprising the six-layer VTX and the three-layer ITK, offers nine precise  
 77 measurements down to  $\theta \approx 32^\circ$ . The ITK endcap supplies up to a maximum of four  
 78 measurement points for tracks at small polar angles. The OTK provides a single high-  
 79 precision measurement point with a large lever arm outside the TPC volume down to a  
 80  $\theta \approx 8.1^\circ$ .

### 81 15.1.1.1 Tracking efficiency

82 With numerous continuous readout layers, pattern recognition and track reconstruc-  
 83 tion in a TPC is generally efficient, even in environments with significant background  
 84 noise. Moreover, the standalone tracking capabilities provided by the VTX and ITK allow  
 85 for the reconstruction of low transverse momentum tracks that do not reach the TPC. The  
 86 ITK's endcap coverage facilitates the reconstruction of tracks to polar angles as low as  
 87 approximately  $\theta \approx 8.1^\circ$ .

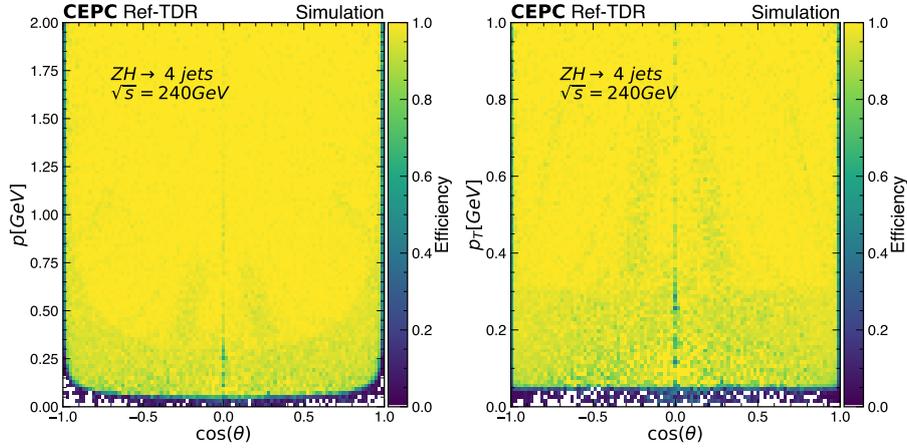

88 Figure 15.1 shows the track reconstruction efficiency as a function of momentum and  
 89 polar angle for simulated high-multiplicity  $ZH \rightarrow 4$  jets at a center-of-mass energy of  $\sqrt{s}$   
 90  $= 240$  GeV. Efficiencies are calculated relative to Monte Carlo tracks originating within  
 91 a 10 cm region around the IP, with transverse momentum  $p_T$  greater than 100 MeV and  
 92  $\cos(\theta)$  less than 0.99. This excludes decays in flight and requires at least 90% purity. On  
 93 average, the combined tracking system achieves a track reconstruction efficiency of 99.7%  
 94 for tracks with momenta greater than 1 GeV across the full polar angle range. In the region  
 95 where  $\cos(\theta)$  is less than 0.05, efficiency decreases due to the membrane cathode situated  
 96 between two rings at the TPC's center.

**Figure 15.1:** Track efficiency as a function of (left) the track momentum and (right) track  $\cos(\theta)$  in the sample of  $ZH \rightarrow 4$  jets at 240 GeV.

97 Figure 15.2 shows the track efficiency in the low momentum region for the process

98  $ZH \rightarrow 4$  jets at 240 GeV. The efficiency is presented as a function of either momentum  
 99 (left) or transverse momentum (right) and  $\cos(\theta)$ .

**Figure 15.2:** Track efficiency in the low momentum region for  $ZH \rightarrow 4$  jets at 240 GeV plotted against 2D plane of momentum (left) or transverse momentum (right) vs.  $\cos(\theta)$ .

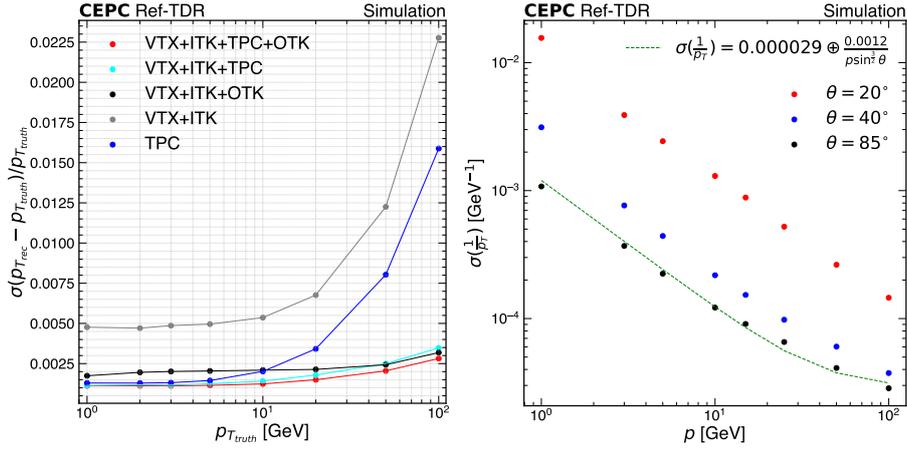

### 100 15.1.1.2 Momentum resolution

101 Figure 15.3 left shows track momentum resolutions across various configurations of  
 102 the tracking system: TPC, VTX+ITK, VTX+ITK+OTK, VTX+ITK+TPC, and VTX+ITK+TPC+OTK.  
 103 The TPC significantly enhances resolution in the low momentum region. In combina-  
 104 tion with the OTK, they provides the longest possible radial lever arm for the track fit,  
 105 improving the resolution at the high momentum region.

106 The momentum resolutions with the full tracking system at different polar angles are  
 107 shown in Figure 15.3 right. The study was conducted with muons generated at fixed polar  
 108 angles of  $\theta = 20^\circ, 40^\circ$  and  $85^\circ$ , with momentum varying from 1 to 100 GeV. For a polar  
 109 angle of  $85^\circ$ , this is compared with the parametric form of  $\sigma_{1/p_T} = a \oplus b/(p \cdot \sin^{3/2} \theta)$ , with  
 110  $a = 2.9 \times 10^{-5} \text{ GeV}^{-1}$  and  $b = 1.2 \times 10^{-3}$ . For high momentum tracks, the asymptotic  
 111 value of the momentum resolution is  $\sigma_{1/p_T} = 3 \times 10^{-5} \text{ GeV}^{-1}$ . In the forward region,  
 112 the momentum resolution is inevitably worse due to the relatively small angle between the  
 113 B-field and the track momentum.

### 114 15.1.1.3 Impact parameter resolution

115 The performance of track's impact parameters is detailed in Section ???. For  $r -$   
 116  $\phi$  impact parameter resolution, the required performance is achieved for tracks with  
 117 momentum down to 1 GeV, while it exceeds expectations for high momentum tracks  
 118 where the asymptotic resolution is close to  $2 \mu\text{m}$ . The  $z$  impact parameter resolution is

**Figure 15.3:** (Left) Track resolution for different configurations of the tracking system at the polar angle of  $85^\circ$ . (Right) Transverse momentum resolution for single muon events as a function of the transverse momentum for different polar angles. The line shows  $\sigma_{1/p_T} = 2.9 \times 10^{-5} \oplus 1.2 \times 10^{-3} / (p \cdot \sin^{3/2} \theta)$ .

119 similar to the  $r - \phi$  resolution and reaches an asymptotic value of  $\leq 3 \mu\text{m}$  for the whole  
 120 barrel region.

121 The effects of beam-induced background events and electronics noise have been  
 122 evaluated and found to be negligible on all the aforementioned tracking performances.

### 123 15.1.2 Leptons

124 The reference detector designed with a focus on particle flow, particularly its highly  
 125 segmented calorimetry system, provides a wealth of data crucial for identifying leptons.  
 126 High-energy electrons and hadrons are expected to generate a substantial number of hits,  
 127 while muons contribute minimally to the calorimeter's energy readings. Electrons can be  
 128 distinguished by their characteristic, narrow electromagnetic shower patterns in the crystal  
 129 ECAL, which correlate with tracks detected in the tracking system. In contrast, muons are  
 130 recognized as particles with minimal ionization in the calorimeter, confirmed by matching  
 131 their tracks with those in both the tracker and the muon detector.

132 An eXtreme Gradient Boosting (XGBoost) classifier [2] has been developed to iden-  
 133 tify muons and electrons against charged hadrons, combining information from different  
 134 sub-detectors. The following is a list of input variables:

- 135 • energy deposit measurements in both calorimeters, divided by the momentum mea-  
 136 sured in the tracker;
- 137 • averaged position of the clusters in both calorimeters weighted by energies;
- 138 • Moliere radius of clusters in both calorimeters;
- 139 •  $\eta$  and  $\phi$  variances of cluster hits in both calorimeters;
- 140 • number of hadronic clusters involved in the PFO;
- 141 • number of muon hits matched to the PFO;

- 142 •  $\Delta R$  between the extrapolated track and hits in the muon detectors;
- 143 • measurements of  $dN/dx$  in TPC;
- 144 • time-of-flight measurement in OTK.

145 The  $dN/dx$  and time-of-flight can offer additional means to differentiate between  
146 electrons, muons, and hadrons by identifying their different masses. More explanation of  
147 these two variables is given in Section 15.1.4.

148 The XGBoost models are trained and tested with the  $ee \rightarrow ZH$  samples, in bins of  
149 the PFO momentum and  $\theta$ . The model outputs the probabilities for each PFO to be a  
150 muon, electron or hadron. Different working points (WPs) are provided:

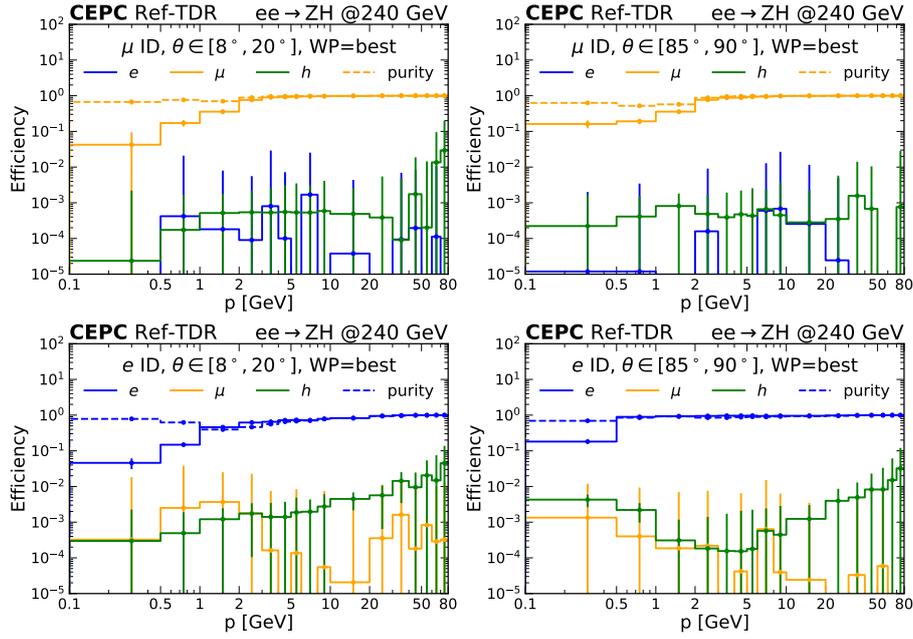

- 151 • WPs with a fixed efficiency, including 50%, 70%, 90% and 98%. WPs for muons  
152 and electrons can be set separately. Muons are identified first: if the PFO has  
153 a probability to be a muon higher than the muon WP, it is identified as a muon;  
154 otherwise, check if its probability to be an electron is higher than the electron WP;  
155 otherwise, it is regarded as a charged hadron.
- 156 • BEST WP, the optimal working point, which identifies the PFO as the flavor that it  
157 has the highest probability.

158 The performance metrics for the BEST WP are illustrated in Figure 15.4. In the  
159 context of muon identification, the efficiency falls below 50% for momenta less than 2  
160 GeV; notably, the efficiency in the endcap region is lower compared to that in the barrel  
161 region. However, as the momentum surpasses 2 GeV, the efficiency rises significantly,  
162 reaching levels above 90% and approaching 100%. The rate of misidentification for  
163 electrons and charged hadrons is predominantly around 0.1% or lower, demonstrating  
164 the system's excellent discriminative capabilities. Similar behaviors can be observed in  
165 electron identification, although the misidentification rate for charged hadrons can be  
166 higher, peaking at approximately 1% at high momenta. The purity of both electron and  
167 muon identifications is predominantly above 90%, indicating a high level of accuracy in  
168 the identification process.

169 As an initial lepton ID approach, further optimizations are anticipated. These will  
170 occur alongside the development of improved event reconstruction algorithms, which  
171 include the electron tracking algorithm using Gaussian sum filters, enhanced clustering  
172 algorithms of energy deposits in the HCAL, and standalone muon track reconstruction in  
173 the muon detector.

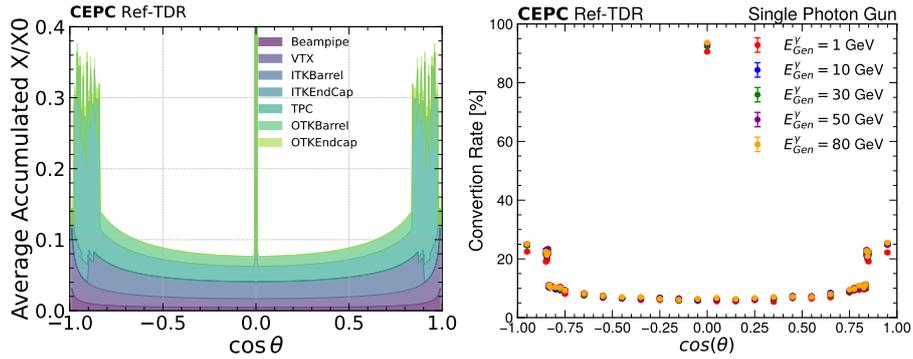

### 174 15.1.3 Photons

175 Photons have similar signatures as electrons in the calorimeter, but generally do not  
176 have matching tracks in the tracker. However, 6–10% of photons in the central region and  
177  $\sim 25\%$  of photons in the forward region convert to  $e^+e^-$  pairs through their interaction  
178 with the materials in front of the calorimeter. Some of these converted photons may have

**Figure 15.4:** The ID efficiency, purity, and misidentification rates with the BEST WP as a function of particle momentum, obtained with the XGBoost models. The top row shows the muon ID; the bottom row shows the electron ID. The left column shows results with  $\theta \in [8^\circ, 20^\circ]$  in the endcap region; the right column shows results with  $\theta \in [85^\circ, 90^\circ]$  in the barrel region. Results are computed with full simulation samples of  $ee \rightarrow ZH$ , combining all decay modes of  $Z$  and  $H$ . In the plots, "h" represents "charged hadron".

179 reconstructed matching tracks. Figure 15.5(left) shows the amount of material in units  
 180 of radiation length, and Figure 15.5(right) shows the photon conversion rates at different  
 181 polar angles.

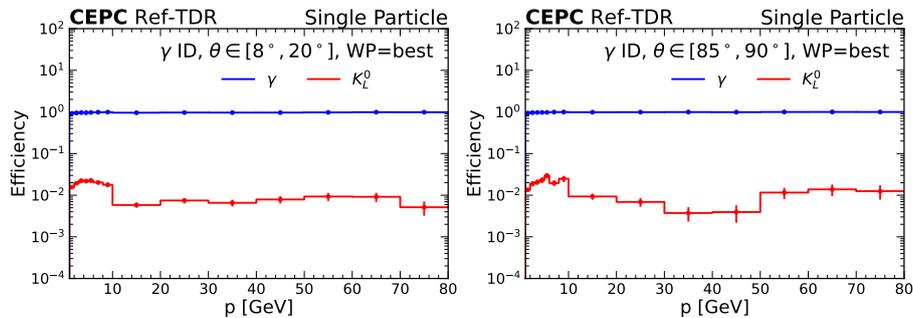

**Figure 15.5:** (Left) The amount of material in the unit of radiation length inside the tracker and (right) the conversion rate of photons with different energies as function of polar angles.

182 For unconverted photons, their performance on the reconstruction efficiency and  
 183 energy resolution is described in Section ???. For photons with energy above 3 GeV,  
 184 the reconstruction efficiency reaches 100%. Because of the very small stochastic term  
 185 inherent to homogeneous calorimeters, the photon energy resolution is excellent in the

186 1–100 GeV range, and reaches well into the sub-percent level for high energy photons.

187 Unconverted photons need to be distinguished from neutral hadrons, which are pre-  
 188 dominantly  $K_L^0$  in the  $e^+e^-$  collision environment. Similar to lepton identification, an  
 189 XGBoost-based algorithm is exploited, using similar input features as those given in Sec-  
 190 tion 15.1.2, except for those from the tracker and muon detectors. The XGBoost models  
 191 are trained in bins of particle momentum and  $\theta$  using single-particle samples of photons  
 192 and  $K_L^0$ . Particles with a probability higher than 0.5 of being a photon are regarded as  
 193 photons.

194 Examples of photon PID efficiency and  $K_L^0$  misidentification rate are shown in Figure  
 195 15.6. The photon ID efficiency remains stable above 90% and approaching 100%. The  
 196  $K_L^0$  misidentification rate is around 2% at  $p < 10$  GeV, and around 1% at  $p > 10$  GeV.  
 197 No major difference is observed between the performances in the barrel region and the  
 endcap region.

**Figure 15.6:** The photon ID efficiency  $K_L^0$  misidentification rate as a function of particle momentum with  $\theta \in [8, 20]^\circ$  in the endcap region (left) and  $\theta \in [85, 90]^\circ$  in the barrel region (right).

198

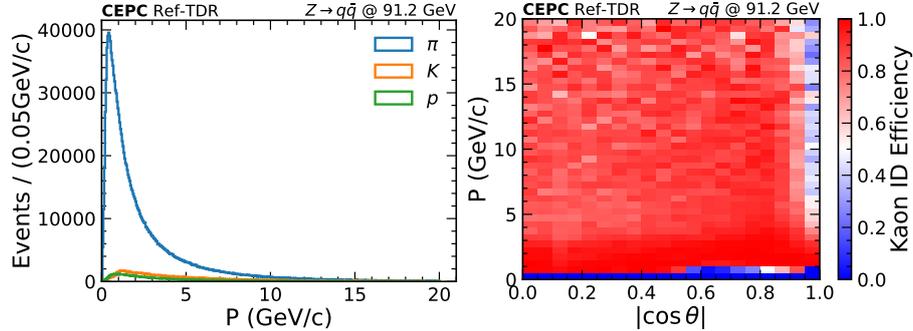

### 199 15.1.4 Charged hadrons

200 Measuring the energy loss of charged particles in the TPC is a powerful tool for  
 201 identifying particle types. Compared to the energy loss method ( $dE/dx$ ), the cluster  
 202 counting method ( $dN/dx$ ) provides better particle identification by reducing statistical  
 203 fluctuations in the charge of secondary ionization. The reconstruction algorithm of  $dN/dx$   
 204 and its separation powers for  $\pi$ ,  $K$  and  $p$  can be seen in ??.

205 Additionally, the time-of-flight (TOF) measurement improves identification, particu-  
 206 larly in the low-momentum region around 1 GeV. The improvement achieved by combining  
 207  $dN/dx$  with the TOF measurement is shown in Section ??.

208 Using  $Z \rightarrow q\bar{q}$  events, the performance of kaon identification is evaluated. Figure  
 209 15.7 (left) presents the momentum distributions of  $\pi$ ,  $K$  and  $p$  particles. Figure 15.7 (right)  
 210 illustrates the identification efficiency of charged kaons as a function of momentum and

211  $|\cos(\theta)|$  based on the  $\chi^2_{\text{Combined}}$ . With  $Z \rightarrow q\bar{q}$  sample, the kaon identification efficiency  
 212 and purity can reach 91% and 86.7%, respectively.

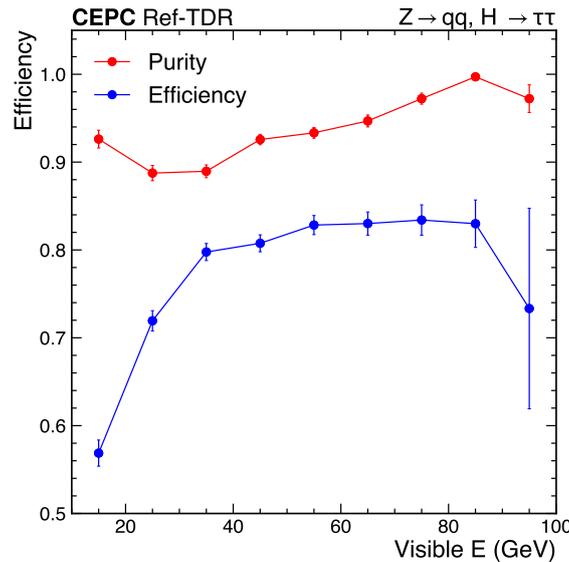

**Figure 15.7:** (Left) Truth momentum distributions of particles  $\pi$ ,  $K$  and  $p$  after requiring no decay in the  $Z \rightarrow q\bar{q}$  sample. (Right) Kaon efficiency in  $Z \rightarrow q\bar{q}$  events is shown as a function of momentum and  $|\cos(\theta)|$ .

213 Similar to lepton identification, XGBoost models are trained using categories of  
 214 particle momentum and  $\theta$ , utilizing only the TOF and  $dN/dx$  data. The overall kaon  
 215 efficiency is improved to around 92%, and the purity is increased to approximately 90.7%.

## 216 15.1.5 Tau leptons

217 Tau leptons, being the heaviest of the leptons, play a distinctive role in Higgs boson  
 218 physics research. The leptonic decays of tau leptons, such as  $\tau \rightarrow e\nu$  and  $\tau \rightarrow \mu\nu$ , are not  
 219 distinguishable from those of electrons or muons. Hadronic decays of tau leptons appear  
 220 in the detector as narrow, pencil-like jets with a low multiplicity of particles. An initial  
 221  $\tau$ -lepton identification algorithm has been devised for hadronic decays. This algorithm  
 222 begins with a seed track whose energy exceeds 1.5 GeV, and gathers charged and neutral  
 223 particles within a small cone of 0.12 radians to form the  $\tau$ -lepton candidate. The invariant  
 224 mass of the particles within this cone must fall within the range of 0.01–2 GeV, aligning  
 225 with the  $\tau$ -lepton mass. Additionally, a discriminant variable based on the longitudinal  
 226 and transverse impact parameters of the leading track is constructed, and this variable must  
 227 be consistent with the non-zero lifetime of the  $\tau$ -lepton. Lastly, the  $\tau$ -lepton candidate  
 228 must be isolated, with the total energy within an annular cone of 0.12–0.31 radians being  
 229 less than 8% of the  $\tau$ -lepton candidate's energy. The primary background consists of  
 230 hadronic jets, which are significant as they can mimic the signal. The efficiency and purity  
 231 as functions of the visible energy of the  $\tau$ -lepton candidate are depicted in Figure 15.8,  
 232 measured from  $e^+e^- \rightarrow ZH$  events with  $Z \rightarrow q\bar{q}$  and  $H \rightarrow \tau^+\tau^-$  decays. For visible  
 233 energy between 10–100 GeV, the efficiency approaches 80%, and the purity surpasses  
 234 90%. The efficiency loss is largely attributed to the sizeable cone size used for the  
 235 isolation requirement. Further optimizations are anticipated to enhance performance.

**Figure 15.8:** The efficiency and purity as functions of the visible energies of the  $\tau$ -lepton candidates. Both the efficiency and purity are determined from  $e^+e^- \rightarrow ZH \rightarrow q\bar{q}\tau^+\tau^-$  events at  $\sqrt{s} = 240$  GeV.

### 236 15.1.6 Vertexing

237 Vertexing plays a crucial role in event reconstruction by identifying the points where  
 238 particles originate and decay. Following LCFIPlus[3], a similar algorithm has been  
 239 developed for this task.

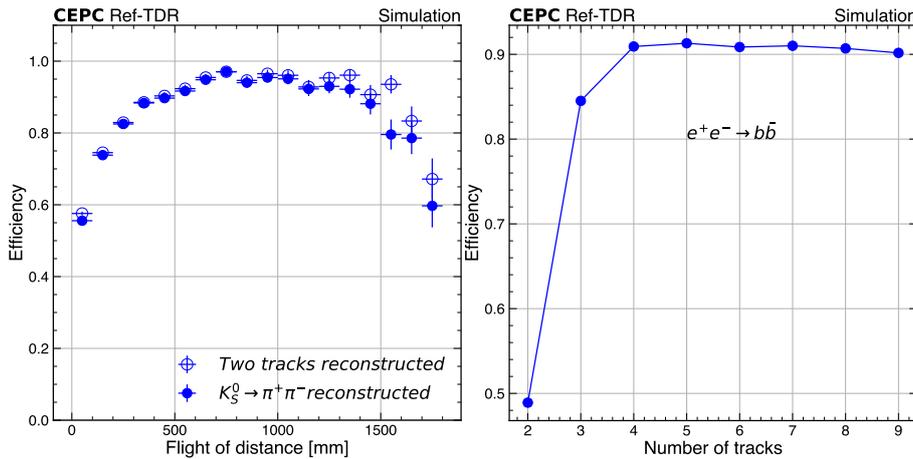

#### 240 15.1.6.1 Vertex efficiency

241 In flavor physics, identifying mesons like  $B$  or  $D$  from a complex track environment  
 242 near the interaction point is challenging. Accurately resolving secondary vertices helps  
 243 suppress combinatorial background and enhance signal purity. **The performance bench-**  
 244 **mark for flavor physics 15.2.7 demonstrates how effectively the vertexing algorithm can**  
 245 **distinguish signal decays from random track combinations.**

246 For particles with a relatively longer lifetime, they can travel through the tracker  
 247 volume before decaying, often producing displaced vertices that serve as key signatures.  
 248 Efficiency in this context is evaluated using  $K_S^0 \rightarrow \pi^+\pi^-$  events. The efficiency is about  
 249 70% and is presented as a function of the particle's flight distance in Figure 15.9 (left).

250 Unlike the exclusive reconstruction in the aforementioned vertexing implementations,  
 251 inclusive reconstruction must be performed without any well-defined characteristics of the  
 252 target events. The algorithm examines all track pairs, discards false candidates based on  
 253 vertex fitting, and then attempts to attach previously discarded tracks to vertex candidates.  
 254 This procedure iterates until no more tracks can be connected to the vertex candidates  
 255 while meeting specific selection criteria. These criteria include the collinearity between  
 256 the candidate's position vector and the total momentum of all associated tracks, as well as

257 constraints on the energy and invariant mass of the tracks linked to the vertex. Due to the  
 258 complexity of the vertex and track scenarios in a jet, defining the efficiency of inclusive  
 259 vertex reconstruction is challenging. To simplify, a true secondary vertex is considered re-  
 260 constructed if it is found within 200  $\mu\text{m}$  of a reconstructed secondary vertex. Additionally,  
 261 if a true vertex has more than two tracks, at least two corresponding reconstructed tracks  
 262 must be used to form this reconstructed secondary vertex. The efficiency for  $e^+e^- \rightarrow b\bar{b}$   
 263 events is 75% and varies with the number of tracks associated with the vertex, as shown  
 264 in Figure 15.9 (right).

**Figure 15.9:** (Left) Reconstruction efficiency of  $K_S^0 \rightarrow \pi^+ \pi^-$  as a function of the  $K_S^0$ 's flight distance; (Right) Reconstructed efficiency of secondary vertex as a function of the number of tracks associated with the vertex in the  $e^+e^- \rightarrow b\bar{b}$  events.

### 265 15.1.6.2 Vertex resolution

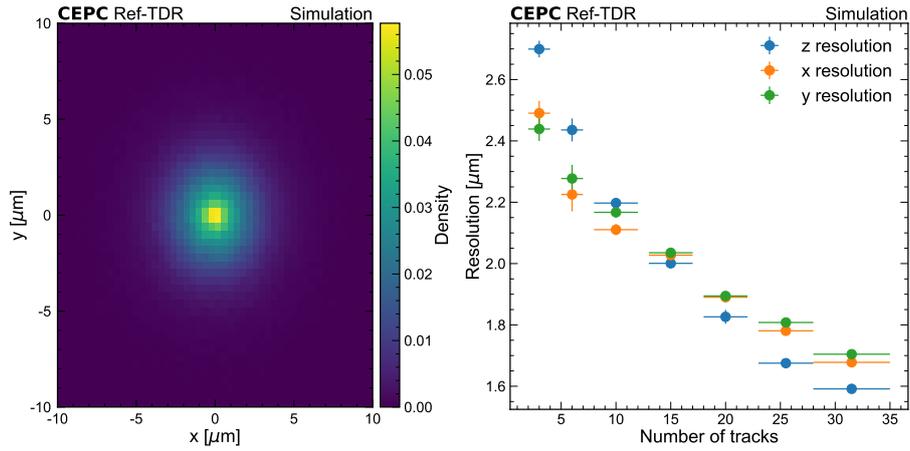

266 The vertex resolution has been assessed using the  $ZH$  samples. Figure 15.10 (left)  
 267 shows the position of the reconstructed primary vertex in the events containing two isolated  
 268 leptons and two  $b$  quarks. The physics interaction has been simulated at the position (0, 0,  
 269 0).

270 Figure 15.10 (right) shows the resolution of the primary vertex position versus the  
 271 number of tracks originating from the primary interaction. The resolution is better than 3  
 272  $\mu\text{m}$  for low multiplicity events and approaches 2  $\mu\text{m}$  for high multiplicity events.

273 The precision of the secondary vertex is studied using  $e^+e^- \rightarrow b\bar{b}$  events. It is exam-  
 274 ined along its orientation to reduce the impact of disturbances caused by boosted events,  
 275 as represented in the Cartesian coordinate system. This approach clearly demonstrates the  
 276 vertexing performance. The orientation is derived from the following equation:

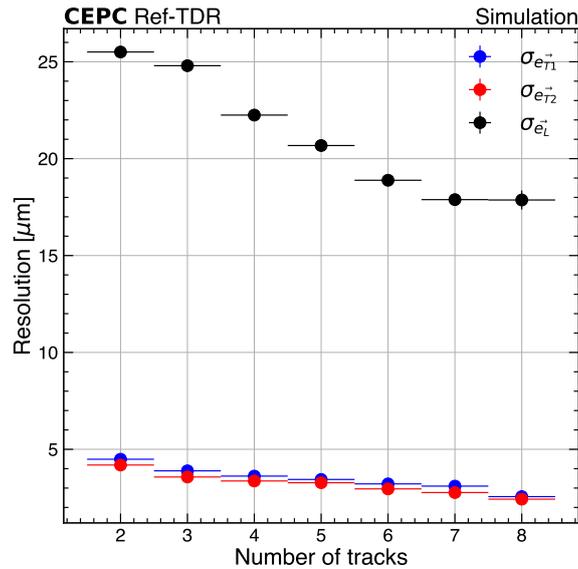

$$\vec{e}_L = \frac{\vec{r}}{|\vec{r}|}, \quad \vec{e}_{T1} = \vec{r} \times \vec{z}, \quad \vec{e}_{T2} = \vec{e}_L \times \vec{e}_{T2} \quad (15.1)$$

277 Here  $\vec{e}_{T1}$  and  $\vec{e}_{T2}$  represent the transverse directions and  $\vec{e}_L$  is the longitudinal direction.  
 278  $\vec{r}$  is the location vector of the corresponding truth vertex and  $\vec{z}$  is the beam direction. The

**Figure 15.10:** Position of the reconstructed primary vertex (left) and resolution of the primary vertex position as a function of the number of tracks originating from that vertex (right).

279 precision improves as more tracks are associated, as shown in Figure 15.11.

**Figure 15.11:** Resolution of the transverse and longitudinal components of the secondary vertices as a function of the number of associated tracks.

280 The overall performance of the reference detector in vertexing is excellent, which was  
 281 already expected based on the single track impact parameter resolutions.

### 282 15.1.7 Jets

283 The design of the reference detector has been optimized for jet energy resolution using  
 284 the particle flow approach, which requires a strong interplay among various sub-detectors.  
 285 This optimization has led to the choice of calorimeters with a high degree of segmentation  
 286 and transverse granularity. To achieve a jet energy resolution that allows for separation of

287  $W$  and  $Z$  decays, sophisticated reconstruction algorithms are necessary.

288 The ee-kt algorithm, also known as Durham algorithm [4], is employed as the baseline  
 289 jet clustering algorithm using the FastJet package [5]. “GenJets” are the clustered truth-  
 290 level Monte Carlo particles produced from the hadronization of partons simulated by  
 291 Pythia [6], including subsequent decay products such as photons, leptons, or other lighter  
 292 hadrons. Neutrinos are excluded from the clustering due to their non-interacting nature,  
 293 which does not contribute to the energy measurements. “RecoJets” are clustered from  
 294 the reconstructed final-state particles using the ee-kt algorithm in the same manner as  
 295 “GenJets”, allowing for a comparison of the clustering process at different levels.

### 296 15.1.7.1 Jet energy and angular resolution

297 The jet reconstruction performance of  $ZH$  events at  $\sqrt{s} = 240$  GeV is analyzed.

298 The GenJet and RecoJet are matched by minimizing the sum of angles between each  
 299 pairs. For a given pair, the relative difference is expressed in terms of the jet energy  
 300 resolution (JER), and the jet angular resolution (JAR). The relative energy difference is  
 301 modelled with the double-sided crystal ball (DSCB) function, while the angular (polar and  
 302 azimuth angle) differences of the GenJet-RecoJet pairs are modelled with the Gaussian  
 303 function. The JER is extracted from the standard deviation ( $\sigma$ ) of the DSCB fit to the  
 304 relative energy difference between RecoJet and GenJet, and the JAR is the  $\sigma$  of the  
 305 Gaussian fit to the angular difference.

306 Figure 15.12 shows the differential jet energy resolution as functions of the  $\cos\theta_{\text{Gen}}$ ,  
 307 azimuth angle and GenJet energy of the  $ZH \rightarrow \nu\nu bb$  events. The JER ranges from 4.5%  
 308 to 6% in the barrel region, and improves as the energy increases, reaching 4.5% for jets  
 309 with energy greater than 90 GeV, as shown in Figure 15.12 right. The JER is slightly  
 310 worse in the endcap region, as shown in Figure 15.12 left.

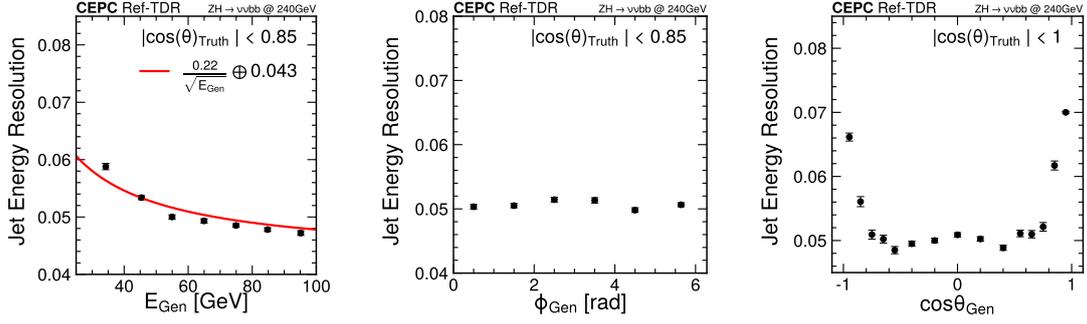

311 Figure 15.13 and 15.14 show the differential jet angular resolution on polar and  
 312 azimuthal angles separately, as functions of the  $\cos\theta_{\text{Gen}}$ , azimuth angle and GenJet energy  
 313 of the  $ZH \rightarrow \nu\nu bb$  events. The JAR is around 0.01 radian for  $\phi$ , and 0.012 radian for  $\theta$ .

### 314 15.1.7.2 Boson mass resolution

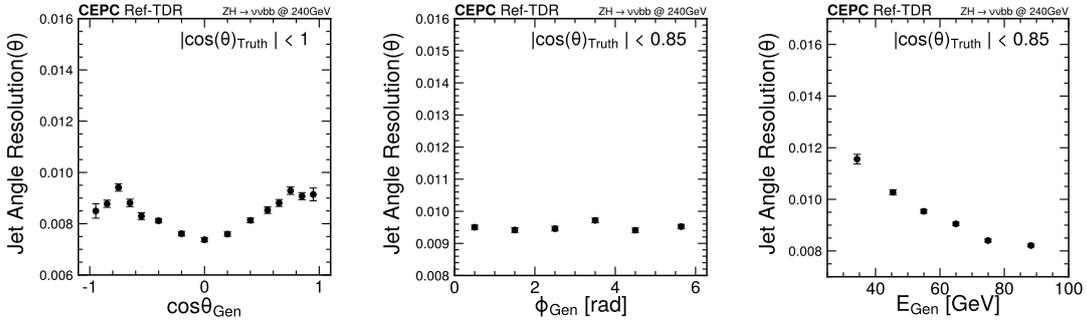

315 Figure 15.15 shows the invariant mass distribution of the Higgs boson in the  $ZH \rightarrow$   
 316  $\nu\nu gg$  sample. When both jets are selected in the barrel region ( $|\cos\theta_{\text{jet}}| < 0.85$ ), the  
 317 Higgs boson mass resolution (BMR) reaches 3.87%, which is better than the design goal  
 318 (4%). In the endcap region, the BMR is approximately 6%.

319 Figure 15.16 shows a clear separation between the  $W$ ,  $Z$ , and Higgs bosons with  
 320 hadronic final states in their reconstructed invariant mass spectrum.

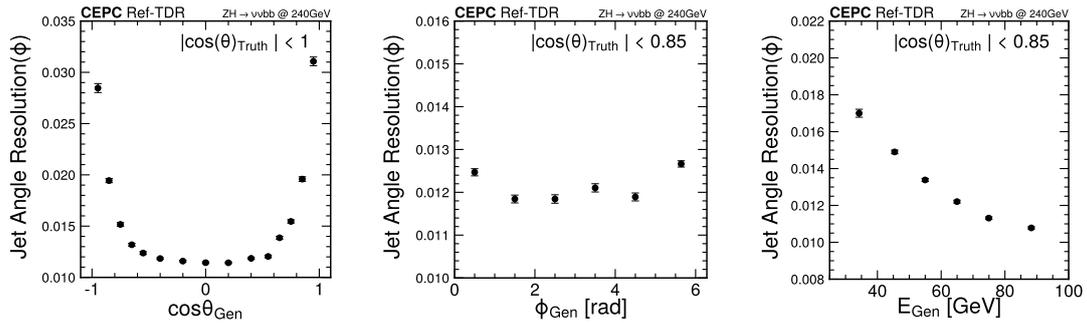

321 With further development of the particle flow algorithm, including the integration of  
 322 PID information, reducing the confusion of photons through  $\pi^0$  identification, correcting

**Figure 15.12:** Jet energy resolution as functions of the  $\cos\theta_{\text{Gen}}$  (left), the azimuth angle (middle), and the GenJet energy (right) for the  $ZH \rightarrow \nu\nu bb$  process. The errors shown are only statistical.

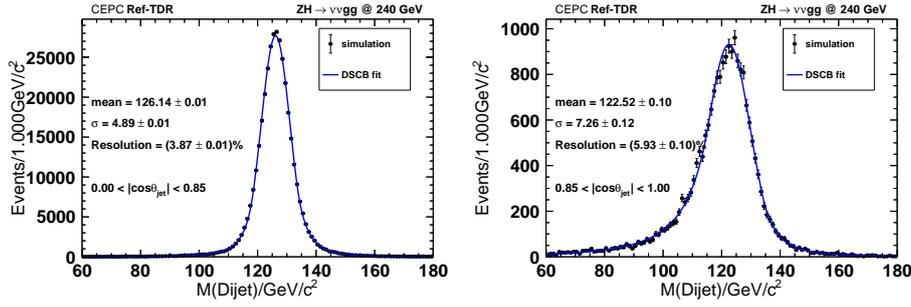

**Figure 15.13:**  $\theta_{\text{jet}}$  resolution as functions of the  $\cos\theta_{\text{Gen}}$  (left), the azimuth angle (middle), and the GenJet energy (right) for the  $ZH \rightarrow \nu\nu bb$  process. The errors shown are only statistical.

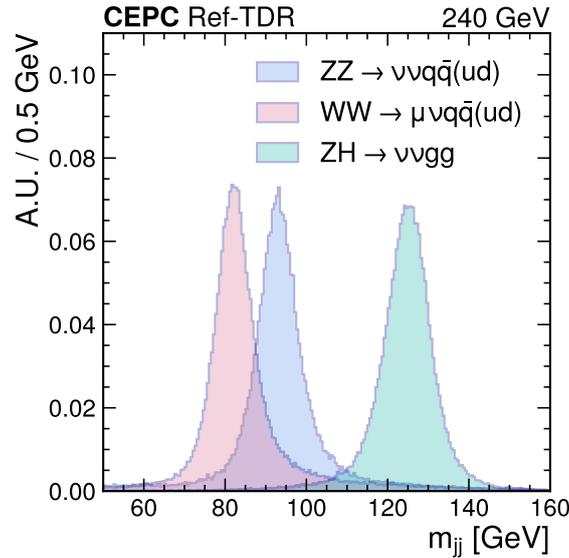

**Figure 15.14:**  $\phi_{\text{jet}}$  resolution as functions of the  $\cos\theta_{\text{Gen}}$  (left), the azimuth angle (middle), and the GenJet energy (right) for the  $ZH \rightarrow \nu\nu bb$  process. The errors shown are only statistical.

323 neutrino component in the semi-leptonic decays of the heavy flavor jets, etc., the BMR  
 324 performance is expected to significantly surpass the design goal.

**Figure 15.15:** Reconstructed di-jet invariant mass distributions in the  $ZH \rightarrow \nu\nu gg$  process at  $\sqrt{s} = 240$  GeV for jets selected in the barrel (left) and endcap (right), separately.

**Figure 15.16:** Reconstructed di-jet mass distribution from  $WW$ ,  $ZZ$  and  $ZH$  processes at  $\sqrt{s} = 240$  GeV.

### 325 15.1.8 Jet flavor tagging

326 Identifying bottom, charm, and other quark decay processes is pivotal for assessing  
 327 the performance of detectors. This capability plays a crucial role in precisely determining  
 328 the Higgs boson couplings and electroweak observables at CEPC. Two specific approaches  
 329 have been explored to quantify the tagging performance.

#### 330 15.1.8.1 Jet flavor tagging with BDT

331 XGBoost is well-suited for jet flavor tagging, offering both strong classification perfor-  
 332 mance and excellent interpretability, which are essential for understanding the underlying  
 333 detector performance.

334 In this study, the XGBoost classifier is set up for three jet categories:  $b$ -jet,  $c$ -jet and  
 335  $uds$ -jet. The variables used in the classification are listed in the Table 15.1. The flavor  
 336 tagging performance in  $e^+e^- \rightarrow q\bar{q}$  events at  $\sqrt{s} = 91.2$  GeV is shown in Figure 15.19, with

337 separate evaluations for  $b$  tagging and  $c$  tagging. The curves represent misidentification  
 338 rates for different jet flavors. For  $b$  tagging, the misidentification rates at  $\epsilon_{b\text{-jet}} = 80\%$   
 339 (50%) are 2.2% (0.11)% for  $c$ -jets and 0.24% (0.03%) for  $uds$ -jets. For  $c$  tagging, the  
 340 misidentification rates at  $\epsilon_{c\text{-jet}} = 80\%$  (50%) are 13.6% (2.9%) for  $b$ -jets and 13.9% (0.78%)  
 341 for  $uds$ -jets.

**Table 15.1:** BDT input variables for jet tagging

Name	Description
VtxLxyz	Decay length of the vertex.
VtxLxyzSig	Significance of the decay length (calculated using the covariance matrix).
VtxMomenta	Magnitude of the momenta of all tracks forming the vertex.
VtxEnergy	Sum of the track energies of the vertex.
VtxMass	Mass of the vertex, calculated using the tracks' four-momentum.
VtxAngle	Angle between the vertex position direction and the total track momentum.
VtxCollinearity	Collinearity between vertex position direction and the total track momentum.
VtxNtrk	Number of tracks forming the vertex.
VtxChi2	Chi-square of the vertex fitting.
VtxNumber	The number of vertices reconstructed in the jet.
VtxTotalTrk	Total number of tracks forming all vertices in the jet.
VtxTotalMass	Total mass of all vertices, computed as the sum of all tracks' four-momenta.
VtxDistance	Distance between the first two vertices.
VtxDistanceSig	Significance of the distance between the first two vertices.
SingleVtxProb	Vertex probability with all associated tracks combined.
MultiVtxProb	For multiple vertices, the probability $P$ is computed as $1 - P = (1 - P_1)(1 - P_2)(1 - P_3) \dots$
TrkTotalMass	Total mass of all tracks exceeding $5\sigma$ significance in $d_0/z_0$ values.
TrkTotalD0Prob	Product of the $d_0$ probabilities of all tracks under the $b/c/uds$ -quark hypotheses using the corresponding $d_0$ distributions.
TrkTotalZ0Prob	Product of the $z_0$ probabilities of all tracks under the $b/c/uds$ -quark hypotheses using the corresponding $z_0$ distributions.
TrkD0Sig	$d_0$ significance of the two tracks with the highest $d_0$ significance.
TrkZ0Sig	$z_0$ significance of the two tracks with the highest $d_0$ significance.
TrkPt	Transverse momentum of the two tracks with the highest $d_0$ significance.

### 342 15.1.8.2 Jet Origin Identification

343 Jet Origin Identification (JOI) [7] is a novel approach for distinguishing jets origi-  
 344 nating from different quarks and gluons. It utilizes an advanced artificial intelligence  
 345 algorithm specifically designed for jet flavor tagging and jet charge measurement. Devel-  
 346 oped using the GNN-based ParticleTransformer framework, JOI enables the simultaneous  
 347 identification of 11 distinct jet species—five quarks, five anti-quarks, and gluons—at the

348 proposed electron-positron Higgs factory.

349 To evaluate JOI performance, we fully simulate  $\nu\bar{\nu}H$  production with  $H \rightarrow u\bar{u}$ ,  
 350  $d\bar{d}$ ,  $s\bar{s}$ ,  $c\bar{c}$ ,  $b\bar{b}$ , and  $gg$  at a center-of-mass energy of 240 GeV, employing the reference  
 351 detector. For each process, one million physics events are generated, with 800,000 used  
 352 for training, 100,000 for validation, and 100,000 for testing. The reconstructed final-state  
 353 particles are clustered into two jets using the  $ee k_t$  algorithm. For each jet, kinematic and  
 354 particle species information—including track impact parameters for charged particles, and  
 355 particle identification described in 15.1.2 is fed into the ParticleTransformer algorithm.  
 356 The comprehensive set of input variables is listed in Table 15.2.

357 The algorithm computes likelihoods for classification into 11 jet categories and  
 358 assigns each jet to the type with the maximum likelihood value. The model is trained  
 359 for 30 epochs, and the epoch yielding the highest accuracy on the validation sample is  
 360 selected for application to the test dataset to extract the final numerical results.

**Table 15.2:** Input variables used in the ParticleTransformer algorithm for jet flavor tagging at the CEPC, including kinematic and particle-specific features.

Variable	Definition
$p_x, p_y, p_z, E$	particle 4-momentum, with energy $E$ derived from PID.
$\Delta\eta$	difference in pseudorapidity between the particle and the jet axis
$\Delta\phi$	difference in azimuthal angle between the particle and the jet axis
$\log p_T$	logarithm of the particle's $p_T$
$\log E$	logarithm of the particle's energy
$\log \frac{p_T}{p_{T(\text{jet})}}$	logarithm of the particle's $p_T$ relative to the jet $p_T$
$\log \frac{E}{E(\text{jet})}$	logarithm of the particle's energy relative to the jet energy
$\Delta R$	angular separation between the particle and the jet axis
$d_0$	transverse impact parameter of the track
$d_0\text{err}$	uncertainty associated with the measurement of the $d_0$
$z_0$	longitudinal impact parameter of the track
$z_0\text{err}$	uncertainty associated with the measurement of the $z_0$
charge	electric charge of the particle
PID	Reconstructed particle type of $e, \mu, \pi, k, p, \gamma$ and neutral hadron

361 Figure 15.17 shows the JOI performance via an 11-dimensional confusion matrix  
 362  $M_{11}$ , with jets classified by their highest likelihood category.

363 Overall, the matrix exhibits approximate quark-anti-quark symmetry and can be  
 364 block-diagonalized into  $2 \times 2$  submatrices, each corresponding to a specific quark species.  
 365 This confusion matrix provides a comprehensive assessment of the model's classification  
 366 performance, highlighting both accurate and misclassified predictions across various jet  
 367 categories.

368 To further quantify JOI performance, we evaluate three distinct scenarios shown in  
 369 Figure 15.18: (1) perfect PID, (2) realistic PID reconstruction, and (3) charged tracks

		CEPC Ref-TDR				H → qq, 125 GeV

		Predicted										

**Figure 15.17:** The confusion matrix  $M_{11}$  with reconstructed identifications of  $e^\pm, \mu^\pm, \pi^\pm, K^\pm, p^\pm$  for  $\nu\bar{\nu}H, H \rightarrow qq$  events at  $\sqrt{s} = 240$  GeV, with the reference detector. The matrix is normalized to unity for each truth label.

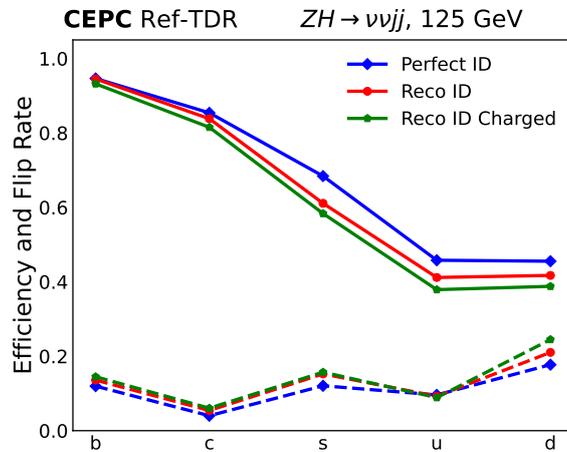

370 only (excluding neutral components). While the realistic PID scenario shows slightly  
 371 degraded performance compared to the ideal case - primarily due to lost PID information  
 372 for low-energy tracks - the b- and c-jet tagging efficiencies remain stable as their vertex  
 373 information ( $d_0$  and  $z_0$ ) provides strong discrimination power. The charged-track-only  
 374 analysis demonstrates that while neutral particle exclusion reduces performance, which  
 375 reflects the impact of electromagnetic calorimeter, the JOI remains functional, confirming  
 376 the robustness of the algorithm even with partial detector information.

377 Compared to the conceptual detector, the reference detector achieves moderate im-  
 378 provement in JOI performance, mostly owing to the calorimeter redesign that enhances  
 379 energy reconstruction.

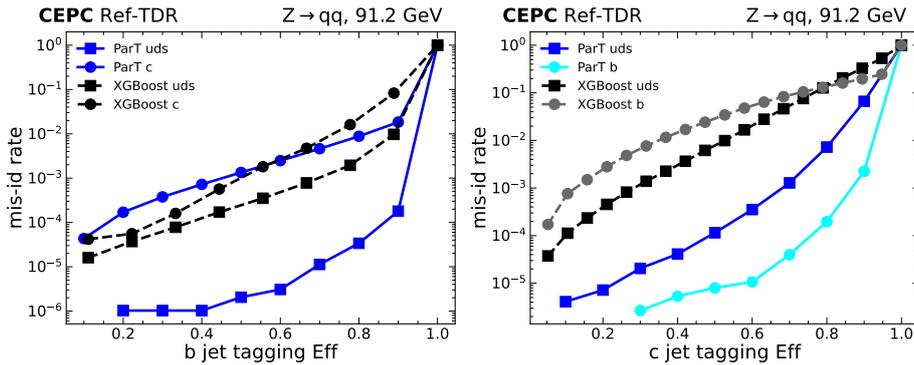

380 Compared to the XGBoost method described in the previous section, the jet tagging  
 381 efficiency versus the misidentification fraction for  $b, c, uds$ , jet, and the comparison to  
 382 XGBoost method is shown in Figure 15.19. Generally, JOI performance is about one order  
 383 of magnitude better compared to the BDT method. This localized performance inversion  
 384 at low b-jet efficiencies is likely an artifact of data sparsity and statistical fluctuations

385 in a rarely optimized or statistically robust region of the ROC curve, rather than true  
 386 superiority. Remarkably, current JOI achieves a b-jet tagging efficiency of 95% with a  
 387 misidentification rate of only 0.1% for light quark jets.

388 This JOI model, optimized within a Higgs-boson production environment, demon-  
 389 strates sufficient universality and generalization capability across diverse kinematic energy  
 390 scales. Critically, its application to  $Z \rightarrow qq$  final states reveals no significant performance  
 391 degradation when compared against JOI models specifically tailored for  $Z \rightarrow qq$  data.  
 392 Furthermore, the model's consistent performance is validated for  $ee \rightarrow qq$  jet samples  
 393 at different center-of-mass energies, specifically for 240 and 360 GeV, highlighting its  
 394 energy-independent robustness beyond the training environment.

**Figure 15.18:** Comparison of JOI performance under three conditions: perfect PID, realistic PID reconstruction, and realistic PID reconstruction using only charged tracks.

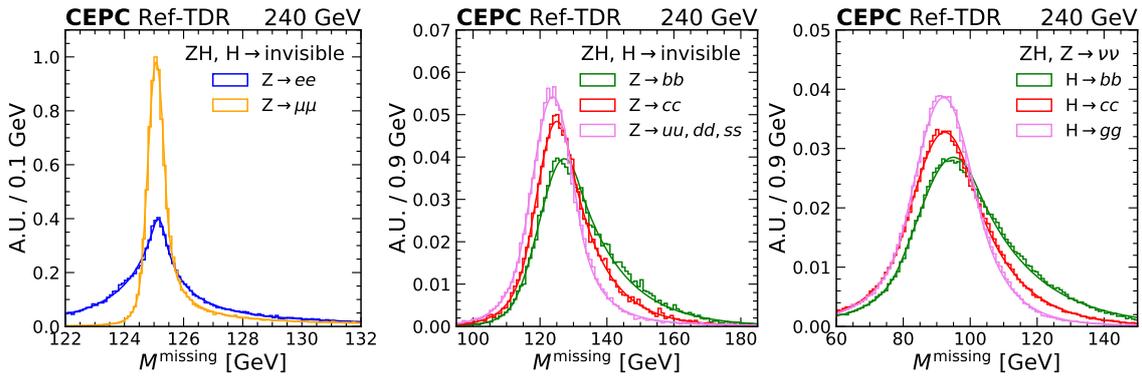

**Figure 15.19:** Jet tagging efficiency versus mis-identification rate for b-tagging (left) and c-tagging (right). Solid for JOI with ParticleTransformer, dashed for XGBoost, solid circle point for mis-id rate from heavy quarks (c or b jets), solid square for mis-id rate from light quarks (uds).

## 395 15.1.9 Missing energy, momentum, mass

396 Neutrinos interact with detectors through weak interactions and evade detection,  
 397 leaving no discernible traces. This characteristic is also attributed to hypothetical dark  
 398 matter particles. Nevertheless, the presence of these elusive particles can be deduced from  
 399 observable particles and plays a crucial role in the CEPC physics program. Approximately  
 400 20% of Z bosons and 30% of W bosons decay into final states that include neutrinos. The  
 401 pursuit of Higgs boson decays into dark matter particles represents a pivotal objective  
 402 of the Higgs factory. Reconstruction of the missing energy, momentum or mass can  
 403 also show the detector coverage capacity and the overall performance of the particle flow  
 404 algorithm to reconstruct all flavors of particles.

405 At the CEPC reference detector, thanks to its excellent energy and momentum reso-  
 406 lution, large coverage of the solid angle, and full knowledge of the initial state, the missing  
 407 energy and momentum can be determined with high precision. The Higgs boson invisible  
 408 decay at  $\sqrt{s} = 240$  GeV is used to illustrate the performance. The Higgs strahlung produc-  
 409 tion is considered, with  $Z \rightarrow \mu\mu, ee$  or  $qq$ , and  $H \rightarrow ZZ^* \rightarrow 4\nu$ . Additionally, the Higgs  
 410 strahlung production with  $Z \rightarrow \nu\nu$  and  $H \rightarrow qq$  is also considered. The distributions  
 411 of the reconstructed missing mass are shown in Figure 15.20. For  $H \rightarrow 4\nu$ , the missing  
 412 mass distributions are always around 125 GeV, while for  $Z \rightarrow \nu\nu$ , they are around 91  
 413 GeV. The missing mass is fitted with double-sided crystal ball functions in each channel.  
 414 The  $Z \rightarrow \mu\mu$  has the best missing mass resolution of 0.288 GeV, while the  $ee$  channel  
 415 gives a slightly worse resolution of 0.40 GeV because the tracking for electrons is more  
 416 complicated due to their higher energy loss in the tracker and higher rate of final state  
 417 radiations. In the  $qq$  channels, light quarks give the best resolution, which is around 6.4  
 GeV for  $Z \rightarrow$  light quarks,  $H \rightarrow 4\nu$  and 9.2 GeV for  $Z \rightarrow \nu\nu, H \rightarrow gg$ .

**Figure 15.20:** The distributions of reconstructed missing mass in the  $ZH$  production, with  $Z \rightarrow ee/\mu\mu, H \rightarrow 4\nu$  (left),  $Z \rightarrow qq, H \rightarrow 4\nu$  (middle) or  $Z \rightarrow \nu\nu, H \rightarrow qq$  (right). The solid lines show the fitted double crystal ball functions. In the middle and right plots, different quark flavors are drawn and fitted separately.

418

## 419 15.2 Physics benchmarks

420 Results of detailed simulation studies of the reference detector are discussed in this  
 421 section. Benchmark studies were conducted at various center-of-mass energies of 91 GeV,  
 422 240 GeV, and 360 GeV, as shown in Table 15.3. These studies cover essential physics  
 423 areas such as Higgs, electroweak, flavor, top, and new physics. For each benchmark, the  
 424 most relevant sub-detectors are highlighted.

**Table 15.3:** Physics Benchmarks and Relevant Detector Performances

Physics Benchmarks	Process @ c.m.e	Domain	Relevant Det. Performance
$H \rightarrow \gamma\gamma$	$ZH @ 240 \text{ GeV}$	Higgs	photon ID, EM resolution
Recoil $H$ mass	$\mu\mu H @ 240 \text{ GeV}$	Higgs	Tracking
$H \rightarrow$ hadronic decays	$ZH @ 240 \text{ GeV}$	Higgs	PID, Vertexing, PFA (+ JOI)
$H \rightarrow$ invisible	$\mu\mu H$ and $qqH @ 240 \text{ GeV}$	Higgs/NP	PFA, MET, BMR
$H \rightarrow$ LLP	$ZH @ 240 \text{ GeV}$	NP	Tracker, Calo, muon detectors
Smuon pair	@ 240 GeV	NP	Tracking
$W$ fusion Xsec	$\nu\nu H @ 360 \text{ GeV}$	Higgs	PFA, $b$ -tagging
Top mass & width	Threshold scan @ $\sim 345 \text{ GeV}$	Top	Beam energy
$A_{FB}^\mu$	$e^+e^- \rightarrow \mu^+\mu^- @ 91.2 \text{ GeV}$	EW	Tracking, muon ID
$R_b$	$Z \rightarrow$ hadronic @ 91.2 GeV	EW	PFA + JOI
CPV in $D^0 \rightarrow \pi^+\pi^-\pi^0$	@ 91.2 GeV	Flavor	PID, vertex, $\pi^0$ , EM resolution

### 425 15.2.1 Event Generation

426 The production of events for the benchmarking analyses includes the generation of a  
 427 comprehensive set of the SM processes. The mass of the SM Higgs boson is set to 125  
 428 GeV.

429 The benchmarking studies primarily use the WHIZARD1.9.5[8] event generator for  
 430 cross-section calculations and Monte Carlo sample generation. Hadronic fragmentation  
 431 is simulated using Pythia6.3 [9]. At the CEPC, Higgs signal production mechanisms  
 432 manifest through three principal channels: Higgsstrahlung ( $e^+e^- \rightarrow ZH$ ),  $W$ -boson  
 433 fusion ( $e^+e^- \rightarrow \nu\nu H$ ), and  $Z$ -boson fusion ( $e^+e^- \rightarrow e^-e^-H$ ).

434 The background processes, excluding Higgs signals, can be broadly classified into  
 435 two major categories based on the number of final-state particles:

- 436 •  $e^+e^- \rightarrow$  2-fermion processes, encompassing leptonic pair production (e.g.,  $e^+e^-$ ,  
 437  $\mu^+\mu^-$ ,  $\tau^+\tau^-$ , ...) and quark-antiquark generation (e.g.,  $q\bar{q}$ )
- 438 •  $e^+e^- \rightarrow$  4-fermion processes, which exhibit significant complexity, necessitating a  
 439 detailed treatment of electroweak interference effects. These 4-fermion backgrounds  
 440 are systematically categorized by their intermediate bosonic contributions:
  - 441 –  $WW$  production ( $e^+e^- \rightarrow W^+W^- \rightarrow 4f$ )
  - 442 –  $ZZ$  production ( $e^+e^- \rightarrow ZZ \rightarrow 4f$ )
  - 443 – Single  $W$  production ( $e^+e^- \rightarrow W e\nu$ )

444 – Single  $Z$  production ( $e^+e^- \rightarrow Zee$ )

445 The comprehensive analysis of cross-sections for all aforementioned processes is  
446 systematically presented in Table 15.4.

447 Notably, the WHIZARD generator demonstrates particular efficacy in handling gauge  
448 boson production processes, interference effects, and initial state radiation correction,  
449 which are critical for precision measurements at CEPC energies.

450 For photon related processes, the WHIZARD generator automatically manages the  
451 initiated and final state photons by default. For example, final states such as  $e^+e^- \rightarrow q\bar{q}\gamma\gamma$   
452 are included in  $e^+e^- \rightarrow q\bar{q}$  process, with an invariant mass and energy cut of 10 GeV for  
453 photon emission. Similarly, the process  $e^+e^- \rightarrow e^+e^-e^+e^-$  considers the effect from  
454 diphoton pair production contribution with the same cut.

455 4-fermion samples are categorized into 40 individual types, ensuring no overlap or  
456 omission during the generation. Without overlap and disregarding the interference, the  
457 overall 4-fermion cross section at 240 GeV is 19.3 pb, and at 360 GeV, the overall cross  
458 section is 14.7 pb. For 6-fermion process other than  $t\bar{t}$ , such as  $ZW$  or  $ZZ$  processes, the  
459 cross section is estimated to be smaller than 20 fb and is not recorded in the table.

460 Then the events go through full simulation and reconstruction chain in CEPCSW. The  
461 detailed information on the samples produced, including their statistics and data paths, is  
462 maintained in a centralized database using the GitLab service provided by IHEP.

## 463 **15.2.2 Higgs mass measurement through recoil mass**

464 Since the discovery of the Higgs boson at the LHC in 2012 [12, 13], extensive efforts  
465 have been made to accurately measure its mass. The most precise measurement of  $m_H$  to  
466 date is  $m_H = 125.11 \pm 0.11$  GeV [14], obtained by the ATLAS experiment. The projected  
467 precision at HL-LHC is 30-50 MeV, depending on different performance assumptions by  
468 the ATLAS and CMS experiments. These measurements rely on specific Higgs decays,  
469 where the signals are either limited by low event yields or affected by significant hadronic  
470 backgrounds and pileup in the hadron collider environment.

471 At CEPC, the Higgs bosons are primarily produced through the Higgs-strahlung  
472 process  $e^+e^- \rightarrow ZH$  with a cross-section of 200 fb at  $\sqrt{s} = 240$  GeV. This study aims  
473 to report the expected precision of  $m_H$  measurement using the  $e^+e^- \rightarrow ZH \rightarrow \mu^+\mu^-X$   
474 events, where  $X$  represents inclusive final states. Due to the well-known initial state  
475 particles and beam energy, this method requires only the measurements of the two muons  
476 from  $Z$ -boson decay, which recoil against the Higgs boson, making the result independent  
477 of the Higgs boson's decay modes. This study is crucial for validating the detector  
478 design and assessing its expected sensitivity, particularly in terms of tracking efficiency,  
479 momentum resolution, and muon identification in the relevant momentum range.

480 Signal events are characterized by two oppositely charged, high-momentum muons.

**Table 15.4:** Cross sections for Higgs production and background processes at  $\sqrt{s} = 240$  GeV and 360 GeV. Note that there are interference between the same final states from different processes after the  $W$  or  $Z$  boson decays, see text. With the exception of the Bhabha process, the cross sections are calculated using the Whizard [8]. The Bhabha cross section is calculated using the BABAYAGA event generator [10] requiring final-state particles to have  $|\cos\theta| < 0.99$ . The  $t\bar{t}$  process are generated by qqbarthreshold [11] generator. Photons, if any, are required to have  $E_\gamma > 0.1$  GeV and  $|\cos\theta_{e\pm\gamma}| < 0.99$ . ISR and FSR effects are included in all the final states.

Process	Cross section @ 240 GeV	Cross section @ 360 GeV
<b>Higgs boson production, cross section in fb</b>		
$e^+e^- \rightarrow ZH$	196.9	126.6

481 As discussed in Section 15.1.1, within the detector acceptance, these muons are expected  
 482 to be efficiently captured and reconstructed with a transverse momentum precision better  
 483 than 0.3%. A signal muon pair forms a  $Z$  boson with an invariant mass close to  $m_Z$   
 484 = 91.19 GeV, while the remaining part of a Higgsstrahlung event consists of the decay  
 485 products of the Higgs. The recoil mass of the muon pair can be calculated using the beam  
 486 energy according to Equation 15.2, without requiring explicit knowledge of the Higgs  
 487 decay components. The recoil mass spectra are shown in Figure 15.21.

$$M_{\text{rec}}^2 = (\sqrt{s} - E_{\mu^-} - E_{\mu^+})^2 - |\vec{p}_{\mu^-} + \vec{p}_{\mu^+}|^2 \quad (15.2)$$

488 To achieve high purity and efficiency in detecting signal events, specific criteria are  
 489 applied to the kinematic variables of the muons. Muons originating from  $Z$  decay are  
 490 expected to have a momentum close to 45 GeV. To select these muons, both lower and  
 491 upper momentum thresholds are set. To suppress soft muons originating from jets or other  
 492 resonances in  $ZH$  events, a minimum momentum threshold of 20 GeV is enforced. Addi-  
 493 tionally, in  $e^+e^- \rightarrow \mu^+\mu^-$  events, muons typically exhibit higher momentum. Therefore,

494 an upper limit of 80 GeV is also applied to enhance the selection’s overall purity.

495 For the event-level requirements, it is essential to select any events resembling a  $Z$   
 496 boson, meaning the invariant mass of the di-muon final state must be within the range of  
 497 50-120 GeV. At the same time, taking into account the phase space of the  $ZH$  process,  
 498 the momentum of the  $Z$  boson should be constrained to avoid being excessively high.  
 499 Therefore, the momentum of the di-muon system is limited to the range of 20-60 GeV.

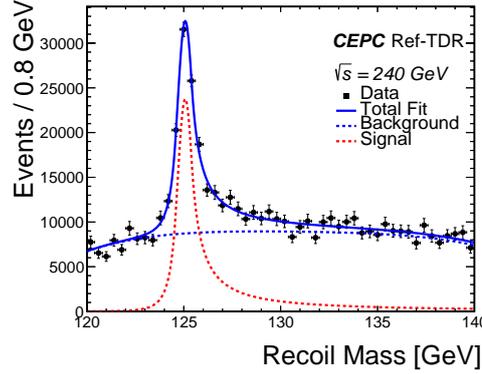

500 Noticing that the  $e^+e^- \rightarrow \mu^+\mu^-$  background process has a significantly larger cross-  
 501 section than both the signal process and other backgrounds, the primary focus of back-  
 502 ground suppression needs to be effectively reducing its contribution. Most muons from  
 503 this background possess nearly half of the center-of-mass energy, so imposing an upper  
 504 limit of 110 GeV on the di-muon energy can serve as a criterion for rejecting these events.  
 505 Furthermore, muons from  $e^+e^- \rightarrow \mu^+\mu^-$  background with ISR may have lower energy  
 506 and could contribute to the  $Z$  peak. To suppress such events, a variable for undetected  
 507 momentum in the beam direction called MEZ, is introduced. If MEZ exceeds 50 GeV, it  
 508 is likely that an ISR photon has been emitted in the final state. By applying these selection  
 509 criteria, this background can be effectively suppressed across nearly the full energy range.  
 510 The event selection criteria are summarized in Table 15.5, in which the four-fermion  
 511 backgrounds are categorized as their final states.

**Table 15.5:** Summary of event selections and cutflow. Four-fermion backgrounds are categorized by their final states

<b>Final States</b>	<b><math>2\nu 2\mu</math></b>	<b><math>4\mu</math></b>	<b><math>2\ell 2q</math></b>	<b><math>2\mu</math></b>	<b><math>\mu\mu H</math></b>
Events number	120000	40000	80000	100000	40000
Muon pair	31.43%	41.70%	29.52%	88.21%	95.58%
$M_{\text{rec}} \in [110, 150]$ GeV	5.83%	8.46%	3.39%	42.04%	88.19%
MEZ $\in [0, 50]$ GeV	4.68%	5.85%	3.02%	25.78%	87.10%
$E_{\mu\mu} \in [0, 110]$ GeV	4.05%	5.13%	2.99%	25.28%	86.58%
$p_{\mu\mu} \in [20, 60]$ GeV	2.67%	3.43%	2.15%	6.49%	78.73%
$m_{\mu\mu} \in [50, 120]$ GeV	2.64%	3.15%	1.74%	6.48%	78.71%

512 After event selections, the shape of the signal  $M_{\text{rec}}$  is modeled using double-sided  
 513 Crystal Ball function. Ideally, the peak position parameter of this function equals  $m_H$ .  
 514 The background is modeled using a Chebyshev polynomial, which is obtained by fitting  
 515 the background-only  $M_{\text{rec}}$  distribution and is fixed in the signal-plus-background model.  
 516 The spectra within the signal region 110-150 GeV and the signal-plus-background shape  
 517 are shown in Figure 15.21.

518 The expected precision of  $m_H$  is estimated by extrapolating the statistics from simu-  
 519 lated signal and background events to their expected yields at an integrated luminosity of  
 520  $20 \text{ ab}^{-1}$ . The statistical uncertainty is  $\Delta m_H = \pm 3.1 \text{ MeV}$ .

**Figure 15.21:**  $M_{\text{rec}}$  distribution and the models for signal and background. The beam energy spread has been included.

- 521 Some foreseeable systematic uncertainties are considered.
- 522 • Momentum scale:  $3 \times 10^7$  radiative return events with  $\mu\mu\gamma$  as final state will be
- 523 generated at  $\sqrt{s}=240$  GeV. This process serves as a standard candle for precision
- 524 measurements, benefiting from very large statistics. With a tracking resolution of
- 525 0.2%, it allows monitoring of the Z peak shift with a relative precision at the level
- 526 of  $10^{-6}$ . Considering that the limiting factors may include the magnetic field and
- 527 the tracker alignment algorithm, the uncertainty of momentum scale is assumed to
- 528 be 2 MeV.
- 529 • Center-of-mass energy: The uncertainty in center-of-mass energy directly propa-
- 530 gates into the Higgs recoil mass spectrum, as shown in Equation 15.2. It can be
- 531 monitored using  $e^+e^- \rightarrow f\bar{f}\gamma$  events, with precise knowledge of the Z boson mass
- 532 and excellent understanding of tracking. For this analysis, it is assumed to be 2 MeV.
- 533 • Beam energy spread: Beam energy spread is expected to be 0.17% at  $\sqrt{s}=240$  GeV
- 534 and has been included in the signal modelling. Its uncertainty can be measured
- 535 using the radiative return events, achieving a precision of 1%. This effects on  $m_H$
- 536 is studied using a perturbed sample and is found to be negligible.
- 537 • Initial state radiation: Initial state radiation can alter the Higgs recoil mass spectrum
- 538 by reducing the effective collision energy. As a theoretical uncertainty in QED, it is
- 539 not considered difficult to handle. For conservatism, the impact on  $m_H$  is assumed
- 540 to be 1 MeV.
- 541 • Beam-induced background: After mixing beam-induced background with signal
- 542 events, the recoil mass spectrum of  $e^+e^- \rightarrow \mu^+\mu^-HX$  is found to be 5 MeV wider
- 543 than before. To account for the beam-background effects temporarily, a nuisance
- 544 parameter of 5 MeV is added to the width parameter in the signal model. Its
- 545 contribution to  $\Delta m_H$  is negligible.

546 These systematic uncertainties contribute an additional 3.7 MeV to  $\Delta m_H$ , resulting in a

547 final precision  $\Delta m_H = \pm 4.8$  MeV. This result can be further improved by combining it

548 with the electron channel, making the CEPC experiment’s target precision for the Higgs  
549 mass measurement achievable.

### 550 15.2.3 Branching ratios of the Higgs boson in hadronic final states

551 According to theoretical predictions, the branching fractions for the decay of a  
552 125 GeV Higgs boson into  $b\bar{b}$ ,  $c\bar{c}$ ,  $gg$ ,  $\tau\bar{\tau}$ ,  $WW^*$ ,  $ZZ^*$  are 57.7%, 2.91%, 8.57%, 6.32%,  
553 21.5% and 2.64%, respectively. The measurements can be conducted simultaneously  
554 together with full hadronic decay modes of  $WW^*/ZZ^*$  and the backgrounds from pro-  
555 cesses with two-fermion and four-fermion final states. The ParticleTransformer(ParT) is  
556 employed for the multi-classification of those different decay modes.

557 Currently, only Higgs production via  $ZH$  process with  $Z$  decaying to a pair of  
558 muons is considered. Each event must contain at least two oppositely charged tracks,  
559 reconstructed as a muon pair. In cases where more than two muons are selected, the muon  
560 pair with the invariant mass closest to the  $Z$  boson mass is chosen as the  $Z$  candidate,  
561 corresponding to a  $Z$ -mass window of 75 GeV to 105 GeV. The invariant mass of the  
562 recoil system, must fall within the Higgs mass window of 110 GeV to 150 GeV. To further  
563 reduce the two-fermion background, the polar angle of muon pair system is required to be  
564 in the range of  $|\cos \theta_{\mu\mu}| < 0.996$ .

565 Table 15.6 and 15.7 presents the event selection efficiencies for various signal and  
566 background processes, detailing the efficiency at each selection step relative to the previous  
567 requirement. In addition, the total efficiency is defined as the ratio of the number of events  
568 satisfying all selection criteria to the total number of events expected from the process  
569 considered (signal or background). For signal processes, a high efficiency of over 80%  
570 is observed. In contrast, two-fermion background processes exhibit a total efficiency  
571 of around 0.3%, four-fermion backgrounds have total efficiencies of 0-3%, while other  
572 backgrounds are found to be negligible.

**Table 15.6:** The cutflow selection efficiency for signal processes.

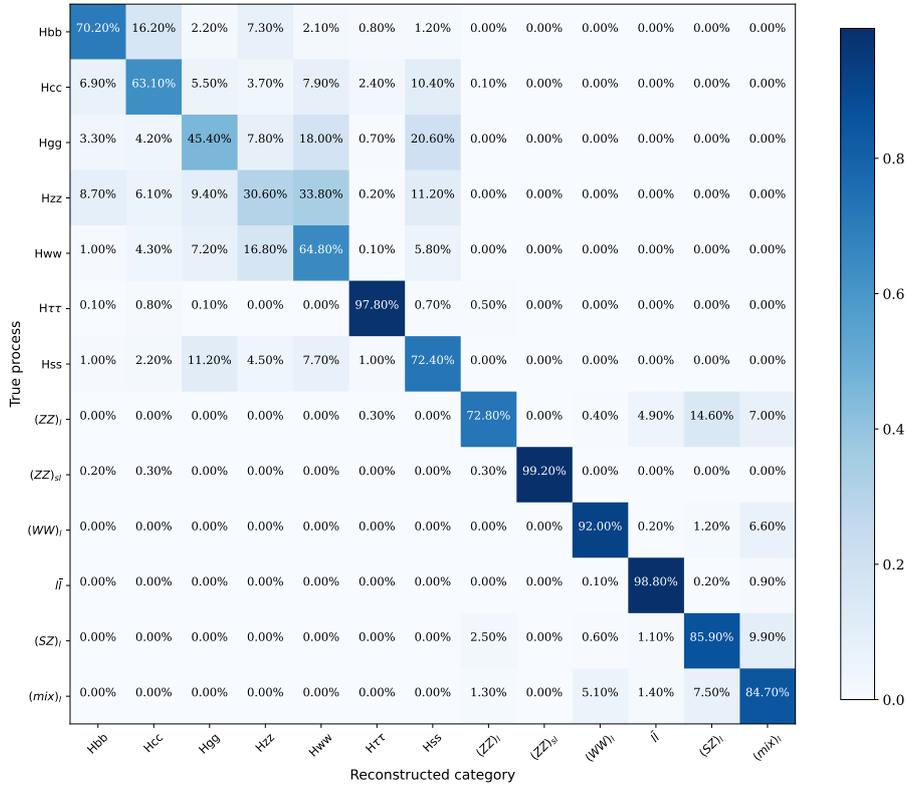

Process	$b\bar{b}$	$c\bar{c}$	$gg$	$\tau\bar{\tau}$	$WW^*$	$ZZ^*$	$s\bar{s}$
Muon pair	93.4%	93.1%	92.9%	94.3%	93.0%	93.1%	93.2%
Isolation	93.0%	93.3%	93.7%	94.6%	93.6%	93.8%	93.5%
$Z$ mass window	96.1%	96.1%	96.1%	93.2%	96.0%	96.0%	96.0%
$H$ mass window	99.6%	99.6%	99.6%	98.5%	99.6%	99.6%	99.6%
$ \cos \theta_{\mu\mu}  < 0.996$	99.6%	99.7%	99.6%	99.7%	99.6%	99.7%	99.7%
Total eff.	82.8%	82.9%	83.0%	81.6%	82.9%	83.2%	83.0%

573 Based on the thirteen classification task, there are thirteen reconstructed categories,  
574 the migration matrix  $M_{\text{mig}}$  is defined as the probability  $\epsilon_{i,j}$  of genuine signal with class  
575  $i$  reconstructed as category  $j$  as shown in Figure 15.22, and can be unfolded for the

**Table 15.7:** The cutflow selection efficiency for background processes.

Process	$(ZZ)_l$	$(ZZ)_{sl}$	$(WW)_l$	$ll$	$(SZ)_l$	$(mix)_l$
Muon pair	46.1%	18.8%	11.0%	11.9%	9.7%	29.3%
Isolation	77.4%	68.8%	98.0%	94.6%	48.2%	96.1%
$Z$ mass window	66.4%	70.4%	34.7%	41.8%	28.3%	16.8%
$H$ mass window	15.6%	16.3%	58.6%	6.6%	29.3%	41.1%
$ \cos\theta_{\mu\mu}  < 0.996$	98.8%	99.5%	98.7%	90.3%	99.0%	99.4%
Total eff.	3.7%	1.5%	2.2%	0.3%	0.4%	1.9%

576 branching fraction measurements. The migration matrix reflects the overall high accuracy  
 577 of the model.

**Figure 15.22:** The migration matrix for the 13 classes is shown. The horizontal axis represents the prediction of the model for each event in the test set, while the vertical axis indicates the true labels. The sum of values in each row equals to 1.

578 By considering all signal and background processes, the numbers of expected events  
 579 for each process can be calculated as in the following:

$$\begin{bmatrix} N_{S1} \\ N_{S2} \\ \dots \\ N_{B1} \\ N_{B2} \\ \dots \end{bmatrix} = (M_{\text{mig}}^T M_s)^{-1} \times \begin{bmatrix} n_{S1} \\ n_{S2} \\ \dots \\ n_{B1} \\ n_{B2} \\ \dots \end{bmatrix} \quad (15.3)$$

580 where  $n_i$  and  $N_i$  are the number of reconstructed events in category  $i$  and number of  
 581 expected events of class  $i$ , respectively. The  $M_s$  is a diagonal matrix containing the  
 582 selection efficiencies, while  $M_{\text{mig}}^T$  denotes the transposed migration matrix.

583 Based on Higgs production via  $ZH$  process with  $Z$  decaying to a pair of muons  
 584 and ParT method, the branching fractions of  $H \rightarrow b\bar{b}/c\bar{c}/gg/\tau\bar{\tau}/WW^*/ZZ^*/s\bar{s}$  at the  
 585 CEPC, with a center-of-mass energy of 240 GeV and luminosity of  $20ab^{-1}$ , are measured  
 586 to be 57.7%, 2.9%, 8.6%, 6.3%, 21.5%, 2.6% and 0.04%, with the statistical uncertainty  
 587 of 0.4% , 6.7% , 2.4% , 1.2% , 1.5% , 18.6%, 266.5% respectively. To account for  
 588 detector response effect, the spatial resolution of each track was adjusted to 10  $\mu\text{m}$ , the  
 589 corresponding systematic uncertainties for the branching fractions are estimated to be  
 590 0.3%, 24.8%, 5.0%, 0.04%, 1.5%, 66.0% and 1636.9%.

**Table 15.8:** The measured branching fractions for the Higgs decays along with their statistical and systematic uncertainties are shown.

Decay channels	$b\bar{b}$	$c\bar{c}$	$gg$	$\tau\bar{\tau}$	$WW^*$	$ZZ^*$	$s\bar{s}$
Br	57.7%	2.9%	8.6%	6.3%	21.5%	2.6%	0.04%
Stat. Un.	0.4%	6.7%	2.4%	1.2%	1.5%	18.6%	266.5%
Syst. Un	0.3%	24.8%	5.0%	0.04%	1.5%	66.0%	1636.9%

## 591 15.2.4 $H \rightarrow \gamma\gamma$

592 The diphoton decay channel of Higgs boson is one important benchmark channel  
 593 in the future Higgs factory. The branching ratio is small due to the origin involving top  
 594 quark and massive boson loop, but it has very clean final state with two energetic photons.  
 595 Regarding the homogeneous ECAL design in this reference detector, an improvement is  
 596 expected in the precision of  $H \rightarrow \gamma\gamma$  measurement.

597 Following the strategy in CDR [15], this analysis focuses on the  $ZH$  production at  
 598  $\sqrt{s} = 240$  GeV, with Higgs decaying to two photons. Three sub-channels are considered  
 599 based on  $Z$  decays:  $Z \rightarrow q\bar{q}$ ,  $\mu^+\mu^-$ , and  $\nu\bar{\nu}$ . The  $Z \rightarrow e^+e^-$  channel is excluded due  
 600 to overwhelming Bhabha background, and  $Z \rightarrow \tau^+\tau^-$  is omitted due to the complexity  
 601 of  $\tau$  identification. The dominant background ( $e^+e^- \rightarrow f\bar{f}$ ) with two ISR/FSR photons  
 602 is considered, while the others, including the Higgs resonant contributions, four fermion

603 processes and reducible backgrounds from photon mis-identification are expected to be  
 604 negligible. The events are generated as described in Sec. . The signal samples are generated  
 605 with full simulation and reconstruction process to have precise detector response, while  
 606 the background samples are processed through the fast simulation with Delphes for large  
 607 statistics.

608 Regarding the kinematic topology of the photons from Higgs boson and fermions  
 609 from Z boson decay, the events are tagged into 3 channels. Event selection are applied to  
 610 reject the backgrounds and mis-tagged events. The leading (subleading) photon energy is  
 611 required to be greater than 30 GeV(20 GeV), and the invariant mass of diphoton needs to  
 612 be within [110, 140] GeV in all three channels. Additional cuts on the angular and energy  
 613 of photons, fermions or missing mass are applied individually depending on the final  
 614 state. The final efficiency and expected yields are listed in Table 15.9. The contamination  
 615 between three sub-channels are examined to be minor ( $<0.3\%$ ) after the event selection.  
 616 A gradient boosted decision tree (BDTG) is trained for event categorization to further  
 617 suppress the background. The distributions in three channels are shown in Figure ?? . The  
 618 chosen variables keeps the same as in [15]. The criteria of category definition is optimized  
 619 by scanning the cut value on BDTG for highest signal significance.

**Table 15.9**

	Selection efficiency	Expected yield at 20 $\text{ab}^{-1}$
$q\bar{q}yy$ signal		
$q\bar{q}yy$ background		
$mmyy$ signal		
$mmyy$ background		
$nnyy$ signal		
$nnyy$ background		

**Table 15.10:** Expected precisions on  $\sigma(ZH) \times \text{Br}(H \rightarrow \gamma\gamma)$  from Asimov data fitting in the three channels (and their combination). The statistical precision includes the contribution from background modeling.

	$\frac{\Delta_{stat}}{(\sigma \times \text{Br})_{SM}}$
$q\bar{q}\gamma\gamma$	0.0403
$\mu^+\mu^-\gamma\gamma$	0.155
$\nu\bar{\nu}\gamma\gamma$	

## 15.2.5 $H \rightarrow$ invisible

In the SM, the Higgs boson can decay to two  $Z$  bosons, each decaying to two neutrinos, with a branching ratio of 0.106%. On the other hand, BSM models predict more scenarios of the Higgs boson invisible decays, including those into dark matter, supersymmetric particles, etc. Compared to the LHC and HL-LHC, future electron-positron colliders would provide much improved sensitivities [16–18] thanks to the low background, and full reconstruction of the missing information.

Searches for the Higgs boson invisible decay are performed with full simulation samples at  $\sqrt{s} = 240$  GeV, described in Section 15.2.4. For the signal, we consider the Higgs strahlung process, with the  $Z$  boson decaying into two muons, two electrons or two quarks; and the Higgs boson decaying into four neutrinos. All background processes are considered, including other Higgs boson production and decay channels, 4-fermion final state and 2-fermion final state processes.

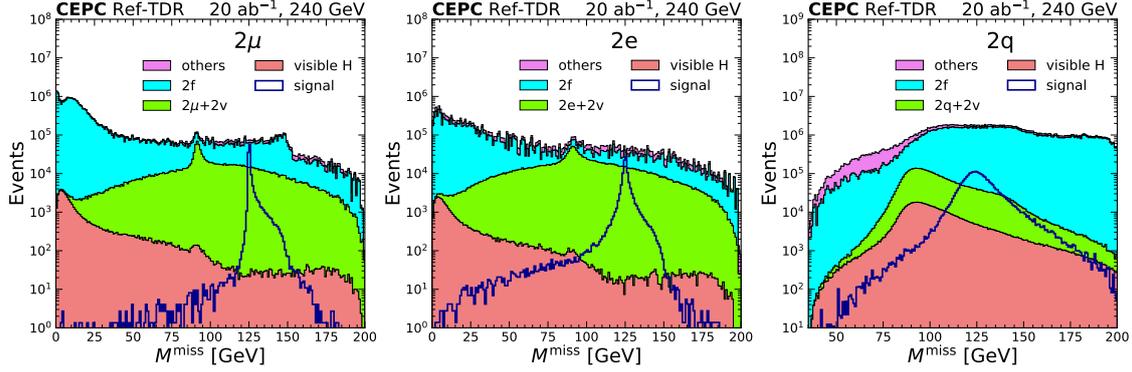

Events firstly pass the baseline selection and are categorized into three channels, selected successively:

- The  $2\mu$  channel: events should contain exactly two PFOs passing the BEST muon ID WP and with  $|\cos\theta| < 0.99$ . The two muons should have the opposite charge, and their invariant mass between 40 and 120 GeV.
- The  $2e$  channel: events should satisfy the same criteria as the  $2\mu$  channel, except for the lepton ID being replaced to that for the electrons.
- The  $2q$  channel: events should not be in the channels above, and should have visible mass between 30 and 130 GeV, and visible momentum between 10 and 80 GeV.

The missing mass  $M^{\text{miss}}$ , introduced in Section 15.1.9, has the strongest sensitivity to the signal among the kinematic variables considered in the analysis. Its distributions are presented in Figure 15.23 for the three channels. The signal processes are distributed around 125 GeV, whereas backgrounds are broadly distributed with different features depending on their physics processes. Especially, the irreducible backgrounds that have the same final states as the signal, shown as the magenta histograms in each plot, is mainly composed of the  $ZZ$  production, and therefore distributed around 91 GeV.

Events are further selected based on  $M^{\text{miss}}$  as well as other variables, including the number and total energy of the charged or neutral particles, visible energy and momentum, missing energy and momentum. The selection efficiency for the signal and background processes are summarized in Table 15.11.

After event selection, an XGBoost model is trained in each channel to discriminate signal and background processes, exploiting all variables mentioned above, as well as lepton impact parameters and jet substructure variables. The distributions of the output scores are shown in Figure 15.24. Most backgrounds are concentrated around zero. The major backgrounds that have large contamination in the high score region are the

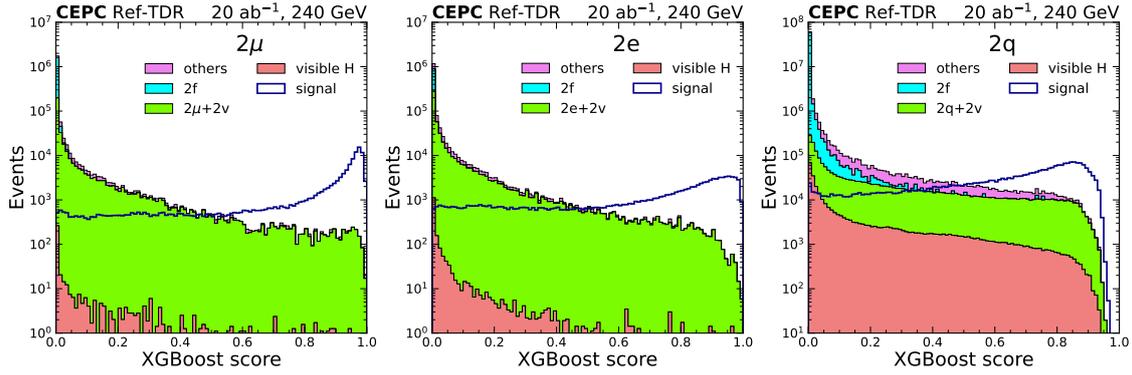

**Figure 15.23:** The  $M^{\text{miss}}$  distributions of signal and background processes in the  $2\mu$  (left),  $2e$  (middle) and  $2q$  (right) channels after baseline selection, estimated with simulation samples. For visibility, the invisible decay branching ratio is set to be 1.

**Table 15.11:** Total generated yields, baseline selection efficiency, further selection efficiency, and selected yields of different signal and background processes, in different channels. For the signal process, only the final state corresponding to the channel is considered.

process		signal	$2(\mu/e/q)+2\nu$	2-fermion	visible H	others
$2\mu$	total yield	1.44e+02	5.68e+06	1.78e+09	4.07e+06	3.79e+08
	Baseline sel	96.1%	32.0%	2.35%	2.55%	0.88%
	Further sel	98.0%	19.8%	3.40%	0.44%	5.31%

658 irreducible backgrounds. The distributions of the XGBoost score are directly fitted to  
 659 perform statistical analyses. Systematic uncertainties including luminosity, beam energy  
 660 measurements, efficiencies and resolutions are estimated with impacts of less than 1%,  
 661 negligible compared to statistical uncertainties. For the SM invisible decay, expected  
 662 uncertainties on the decay branching ratio and statistical significances are computed; for  
 663 BSM scenarios, the SM signal is added as an additional background, and expected upper  
 664 limits (UL) at 95% confidence level on the decay branching ratio are computed.

665 Results are shown in Table 15.12. In general, the  $2q$  channel has the highest sensitivity.  
 666 The combined significance is expected to reach  $4.4\sigma$  with  $20\text{ ab}^{-1}$ , significantly improved  
 667 in comparison to Ref. [18], thanks to the multivariate analysis approach.

**Figure 15.24:** The XGBoost score distributions of signal and background processes in the  $2\mu$  (left),  $2e$  (middle) and  $2q$  (right) channels. For visibility, the invisible decay branching ratio is set to be 1.

**Table 15.12:** Expected relative uncertainties, statistical significance of the SM Higgs boson invisible decay, and upper limits on the BSM invisible decay branching ratio for  $20 \text{ ab}^{-1}$  in each channel and all channels combined.

channel	uncertainties	significance	UL
$2\mu$	$-43\% / +44\%$	$2.4 \sigma$	$0.093\%$
$2e$	$-62\% / +65\%$	$1.6 \sigma$	$0.14\%$
$2q$	$-31\% / +31\%$	$3.3 \sigma$	$0.064\%$
combine	$-23\% / +23\%$	$4.4 \sigma$	$0.049\%$

## 668 15.2.6 $R_b$ at $Z$ pole

669 The measurement of  $R_b$ , which represents the relative partial decay width of the  $Z$   
 670 boson into  $b\bar{b}$  final states ( $R_b = \frac{\Gamma_{b\bar{b}}}{\Gamma_h}$ , where  $\Gamma_{b\bar{b}}$  is the partial decay width of  $Z \rightarrow b\bar{b}$  and  
 671  $\Gamma_h$  is the total hadronic decay width), holds paramount significance in the vast landscape  
 672 of particle physics. It serves as a fundamental cornerstone for testing the Standard Model  
 673 (SM) and a highly sensitive probe for uncovering new physics phenomena beyond its  
 674 current framework [19–22].

675 The current experimental landscape for  $R_b$  measurements is shaped by data from  
 676 experiments conducted at renowned facilities such as the Large Electron - Positron Collider  
 677 (LEP) and the Stanford Linear Collider (SLC) [23–28].

678 At the Circular Electron-Positron Collider (CEPC), jets play a pivotal role in the  
 679 measurement of  $R_b$  [29, 30]. Jets are formed when quarks and gluons undergo the process  
 680 of hadronization, and their properties can be meticulously analyzed to infer the flavor of  
 681 the originating quark. Jet flavor tagging, therefore, emerges as a crucial technique in this  
 682 measurement, which can be a key benchmark reflecting the vertex detector performance.  
 683 In this study, the jet flavor tagging is performed using the advanced tagging algorithm  
 684 called the JOI tagger. More technical details can be found in Sec. 15.1.8.2. Instead of  
 685 using the full 11 categories as in the Sec. 15.1.8.2, several categories are merged with

		CEPC Ref-TDR			Z → qq, 91.2 GeV			
Truth	b	0.950	0.038	0.012				
	c	0.018	0.861	0.121				
	q	0.003	0.040	0.957				
			Predicted					
			b	c	q			

**Figure 15.25:** The confusion matrix after category merging. This confusion matrix is produced with  $Z \rightarrow b\bar{b}$ ,  $Z \rightarrow c\bar{c}$  and  $Z \rightarrow q\bar{q}$  (light-quarks) sample generated at  $\sqrt{s} = 91.2$  GeV.

686 the following scheme: quark and anti-quark categories for the same flavor are merged;  
 687 categories besides  $b$  and  $c$  quark are merged into the light-quark category. With such a  
 688 merge scheme, a total of 11 categories are reduced to 3 ones.

689 In this analysis, the criteria used to tag  $b$ ,  $c$ , and  $q$  (light-quarks) is the same as  
 690 Sec.15.1.8.2 to calculate the confusion matrix, thus, the tagging efficiencies could be  
 691 obtained from a 3-dimensional confusion matrix ( $M_3$ ). This confusion matrix is calculated  
 692 from a set of simulated samples corresponding to  $Z \rightarrow b\bar{b}$ ,  $Z \rightarrow c\bar{c}$ ,  $Z \rightarrow s\bar{s}$ ,  $Z \rightarrow d\bar{d}$ ,  
 693 and  $Z \rightarrow u\bar{u}$  with such the same convention as the original 11-dimensional matrix, where  
 694 more detail of the convention could be found in Sec.15.1.8.2. Such a matrix is shown in  
 695 Figure 15.25, and is further used in  $R_b$  and  $R_c$  measurement.

696 The measurement of  $R_b$  at CEPC is accomplished through the implementation of the  
 697 double-tagging method. This method is based on a meticulous counting of the number of  
 698 jets of a particular flavor in two distinct scenarios: single-tagged jets and double-tagged  
 699 jet pairs. The observed number of single - tagged jets of flavor  $i$  ( $N_s^{i,obs}$ ) and double -  
 700 tagged jet pairs ( $N_d^{i,obs}$ ) are intricately related to  $R_b$ ,  $R_c$ ,  $R_q$  ( $R_q = 1 - R_b - R_c$ ) and the  
 701 tagging efficiencies ( $\varepsilon_{ij}$ ) through the following equations [29–31]:

$$N_s^{i,obs} = 2N^{h,pro} \cdot (R_b\varepsilon_{ib} + R_c\varepsilon_{ic} + R_q\varepsilon_{iq}) \quad (15.4)$$

$$N_d^{i,obs} = N^{h,pro} \cdot [R_b\varepsilon_{ib}^2 + R_c\varepsilon_{ic}^2 + R_q\varepsilon_{iq}^2] \quad (15.5)$$

702 Here,  $N^{h,pro}$  is the total number of  $Z$  boson hadronic events produced in collisions.  
 703 These equations form the foundation of the double-tagging method, allowing for a precise  
 704 determination of  $R_b$  based on the measured jet counts and known tagging efficiencies  
 705 which are obtained from the confusion matrix.

	$\sigma_{R_b}(10^{-6})$	$\sigma_{R_c}(10^{-6})$	$\sigma_{R_q}(10^{-6})$	Flavor tagging method
LEP+SLC	659	3015	–	–
FCCee	2.1	–	–	–
CEPC (template fit)	1.2	2.3	2.1	LCFIPlus
CEPC (PartNet)	1.3	1.4	–	ParticleNet
CEPC (JOI)	1.3	1.5	–	JOI

**Table 15.13:** Comparison of statistical uncertainties of  $R_b$ ,  $R_c$ ,  $R_q$  measurement from difference methods.

706 With the definition above, for each flavor jet ( $b$ ,  $c$ , and  $q$ ), there are two equations  
 707 associated, resulting in a total of six equations. These equations are over-determined,  
 708 meaning there are more equations than unknowns, which can be solved using the least-  
 709 squares method. To assess the reliability of the  $R_b$  measurement, a toy Monte Carlo  
 710 approach is employed to calculate the statistical uncertainty. In this approach, a large  
 711 number of  $Z$  hadronic decay events ( $10^{11}$  in this study) are sampled according to the  
 712 Poisson distribution. These events are then further sampled into three categories ( $b\bar{b}$ ,  $c\bar{c}$ ,  
 713 and  $q\bar{q}$ ) according to the multinomial distribution. The statistical uncertainty provides a  
 714 measure of the reliability of the  $R_b$  measurement, indicating the range within which the  
 715 true value of  $R_b$  is likely to lie.

716 A comparison of statistical uncertainties of  $R_b$  and  $R_c$  measurement from different  
 717 experiments and methods is shown in Table 15.13. The results of the  $R_b$  and  $R_c$  measure-  
 718 ments at CEPC demonstrate a significant improvement compared to previous experiments  
 719 such as LEP/SLC. The double-tag method at CEPC achieves a precision comparable to  
 720 that of the template fit method [31]. Only statistical uncertainty is evaluated in the cur-  
 721 rent analysis. Both theoretical variations, such as modeling of quark radiation and gluon  
 722 splitting ( $g \rightarrow b\bar{b}$ ), and experimental corrections on track and PFO properties are the main  
 723 source of systematic uncertainty in the  $R_b$  ( $R_c$ ) measurement. Such uncertainties have a  
 724 much higher impact compared to statistical uncertainty and need more detailed studies.

## 725 15.2.7 CP violation searches in $D^0 \rightarrow h^- h^+ \pi^0$

726 The branching ratio of  $Z$  boson decays to a pair of charm and bottom quarks are  
 727  $\text{BR}(Z \rightarrow c\bar{c}) \simeq 12\%$ ,  $\text{BR}(Z \rightarrow b\bar{b}) \simeq 15\%$  in the SM, respectively, which suggests that  
 728 the CEPC  $Z$ -pole operation mode could also serve as a charm and bottom factory. A  
 729 comparison of the expected yields of charm and bottom hadrons from BESIII, Belle-II,  
 730 LHCb and CEPC  $Z$ -pole operation mode is shown in Table 2 in Ref. [32].

731 The yields of heavy flavour hadrons from CEPC are larger than those from existing  
 732 electron-positron colliders by one or several orders of magnitudes, and CEPC can also  
 733 access heavy hadrons that other electron-positron colliders cannot produce. Due to the

734 large production cross-section in hadron collider, LHCb can produce much more heavy  
735 flavour hadrons than CEPC, however, the complicated collision environment makes the  
736 reconstruction and selection efficiency at LHCb much smaller than CEPC. Therefore,  
737 CEPC can remain advantages in many cases, especially for bottom hadron decays, or  
738 decays contain neutral particles. Given the CEPC's high luminosity, low background, and  
739 excellent detector performance, CEPC may significantly enhance the precision of certain  
740 studies in heavy flavour physics.

741 In order to reconstruct heavy flavour decay events, charged track measurement, vertex  
742 reconstruction, particle identification, and neutral particle reconstruction are crucial. Here,  
743 we choose to use  $D^0 \rightarrow h_1^- h_2^+ \pi^0$  (where “ $h_{1/2}$ ” represent either a Kaon or a pion) decays  
744 as benchmark decays, to demonstrate the impact of detector performance to flavour physics  
745 studies.

746 CP violation in Charm meson decays was recently discovered by LHCb experiment  
747 [33], however, it only discovered in two-body decays. Multi-body decays provides rich  
748 resonance structures, which could help us understand the source of CP violation. The  
749 sensitivity of CP violation searches largely depend on the sample statistics. Due to  
750 the large branching fraction of the singly-Cabibbo-suppressed decay  $D^0 \rightarrow \pi^- \pi^+ \pi^0$ , it  
751 potentially could be a sensitive channel for studying CP violation in multi-body decays,  
752 and the Cabibbo-favoured decay channel  $D^0 \rightarrow K^- \pi^+ \pi^0$  will serve as a reference channel.

753 In order to get a reasonable estimation of the yields, a quantitative study of the  
754 efficiency for reconstructing and selecting  $D^0$  decays has to be proceed. We produced  
755 inclusive  $Z \rightarrow qq$  full simulation sample using CEPCSW. Then from this sample, we  
756 could reconstructed two charged tracks that came from a same vertex that displaced from  
757 the primary vertex. For  $D^0 \rightarrow h^- h^+ \pi^0$  decays, an additional neutral pion need to be  
758 reconstructed using two photon clusters recorded by ECAL, an invariant mass constraint  
759 need to be applied to the two charged tracks and the neutral pion. The neutral pions from  
760 flavour physics interested decays usually has smaller momentum, therefore the photons  
761 from those pions also have relatively low momenta (Figure 15.26 a), and the single  
762 photon reconstruction efficiency is relatively low for low energy photons , therefore, in  
763 order to suppress background and maintain efficiency, the following strategy were used  
764 to reconstruct neutral pions: firstly, using generator level MC sample, the open angle  
765 distribution between two photons is obtained (Figure 15.26 b), we choose  $10^\circ$  as the  
766 criteria to suppress random combinations. secondly, a photon with energy larger than  
767 0.5 GeV is selected as the leading photon, thirdly, a second photon is searched closed to  
768 the leading photon, with energy requirement to be  $E > 0.1$  GeV. With this selections,  
769 most of the background can be suppressed, while the efficiency can be  $\mathcal{O}(0.1)$ .

770 A dedicated PID efficiency study was then performed using dNdx only PID and  
771 dNdx+TOF PID information, to estimate the impact of different detector designs to the  
772 final efficiency. A preliminary qualitative estimate of several  $D^0$  decay yields is shown in

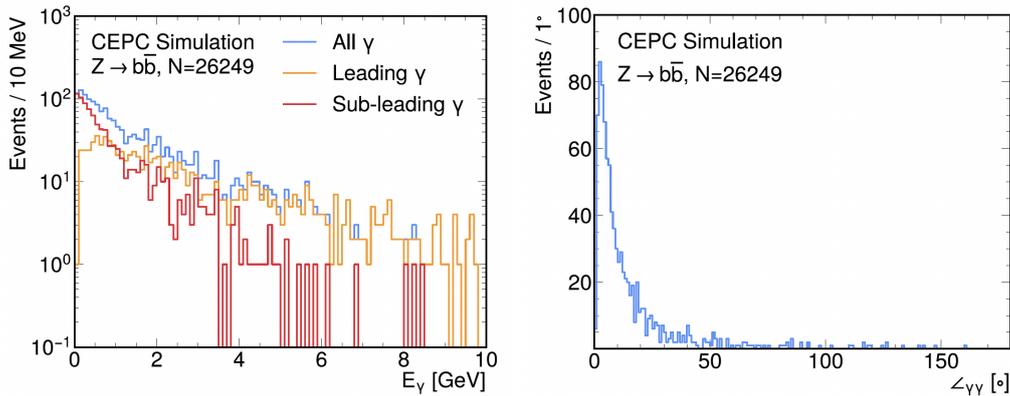

Figure 15.26

773 Table 15.14. These decays have fully hadronic final states. Data collected by the LHCb  
 774 experiment during its Run-2 period (approximately  $6 \text{ fb}^{-1}$ ) and the expected data to be  
 775 collected over the entire lifetime of the LHC and LHCb (approximately  $300 \text{ fb}^{-1}$ ), as  
 776 well as the number of corresponding decay modes expected to be collected at the CEPC  
 777  $Z$ -pole operation mode are shown. Additionally, we compared the number of relevant  
 778 decay modes reconstructed in certain physics analyses.

779 Despite the lower reconstruction efficiency, LHCb has a significant statistical advan-  
 780 tage over CEPC for  $D^0$  decays to fully charged hadronic final states. However, from the  
 781 comparison listed in Table 15.14, it can be concluded that as a hadronic collider, LHCb  
 782 experiment has particularly low efficiency for reconstructing  $\pi^0$  particles, and for decay  
 783 modes with  $\pi^0$  final states, LHCb does not have a statistical advantage over CEPC in terms  
 784 of reconstructed decay events. Therefore, conducting flavor physics research involving  
 785  $\pi^0$  particles at the CEPC, such as searching for CP violation in the  $D \rightarrow \pi\pi\pi^0$  decay, is  
 786 promising in achieving measurement results comparable to LHCb’s precision.

## 787 15.2.8 Top quark mass and width

788 The top quark, the most massive elementary particle in the Standard Model, has  
 789 a strong coupling to the SM Higgs boson, providing an excellent probe for precision  
 790 measurements and new physics beyond the SM. To date, the top quark mass has been  
 791 measured in hadron collider experiments, such as those conducted at the Tevatron and the  
 792 Large Hadron Collider (LHC), through direct reconstruction of the invariant mass of decay  
 793 products. The top quark mass precision till now is down to less than a half of GeV [37–40]  
 794 and it is mainly limited by the systematic uncertainties, such as jet energy scale, which are  
 795 very challenging to be reduced.

796 Looking ahead, electron-positron colliders will enable not only direct reconstruction  
 797 measurements but also an alternative approach using a threshold scan of the center-of-mass  
 798 energy near the  $t\bar{t}$  production threshold. At the energy threshold of  $t\bar{t}$ , the  $t\bar{t}$  production

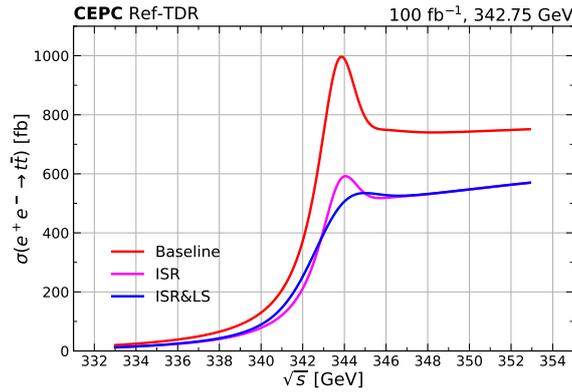

**Table 15.14:** The number of ( $D^0$ ) and related fully hadronic final state decay modes produced at the LHCb experiment during its Run-2 period (approximately  $6 \text{ fb}^{-1}$ ) and the expected data to be produced over the entire lifetime of the LHC and LHCb (approximately  $300 \text{ fb}^{-1}$ ), as well as the number of corresponding decay modes expected to be produced at the CEPC  $Z$ -pole operation mode. The total yields at LHCb is estimated using the cross-section measured by Ref. [34], the reconstructed and selected events from LHCb are obtained from Ref. [35, 36], while the reconstruction and selection efficiency at CEPC is assumed to be 10%.

Decays	LHCb ( $6 \text{ fb}^{-1}$ )	LHCb ( $300 \text{ fb}^{-1}$ )	CEPC (4 Tera $Z$ )

Reco. & Sel. $D^0 \rightarrow K^- \pi^+ \pi^0$	$1.9 \times 10^7$ [36]	$9.6 \times 10^8$	$4.4 \times 10^9$

799 cross-section increases sharply as shown in Fig. 15.27 and is highly sensitive to the top  
800 quark mass, its decay width, and the strong coupling constant,  $\alpha_S$ . The threshold scan  
801 method has been extensively discussed in the literature as a precise method for determining  
802 the top quark mass in the scenarios of ILC, CLIC, FCC-ee and CEPC [41–46].

803 In the CEPC setup, realistic scan strategies at the threshold are discussed to maximise  
804 the sensitivity to the measurements individually and simultaneously in the CEPC scenarios  
805 assuming a total luminosity limited to  $100 \text{ fb}^{-1}$  in Ref. [46]. With the optimal scan for  
806 individual property measurements, the top quark mass precision is expected to be 7  
807 MeV considering only the statistical uncertainty. Taking into account the systematic  
808 uncertainties from theory, width,  $\alpha_S$ , experimental efficiency, background subtraction,  
809 beam energy and luminosity spectrum, the top quark mass can be measured at a precision  
810 of 21 MeV optimistically and 54 MeV conservatively at CEPC, as shown in Tab. 15.15.

811 In Tab. 15.15, two scenarios of systematic uncertainties are considered, the optimistic  
812 and conservative ones. The experimental efficiency of future detectors is not yet known. To  
813 address this, we consider several possible scenarios for the level of uncertainty: 0.5%, 1%,  
814 3%, and 5%. This uncertainty directly affects the signal yields, resulting in corresponding  
815 measurement uncertainties in the top quark mass of 4 MeV, 9 MeV, 26 MeV, and 44 MeV,  
816 respectively, which can be leading among all systematics uncertainties. The theoretical  
817 calculation uncertainty is assumed to be 3%, based on conservative estimates from Ref. [47,

**Figure 15.27:** Cross section of  $t\bar{t}$  production as a function of center-of-mass energy at CEPC [46], including the cross-section values without ISR or LR (baseline), the ones with ISR only and the ones with both ISR and LS.

Source	$m_{top}$ precision (MeV)	
	Optimistic	Conservative
Statistics	7	7
Theory	8	24
Quick scan	2	2
$\alpha_S$	16	16
Top width	5	5
Experimental efficiency	4	44
Background	1	3
Beam energy	2	2
Luminosity spectrum	3	6
Total	21	54

**Table 15.15:** The expected statistical and systematical uncertainties of the top quark mass measurement in optimistic and conservative scenarios at CEPC.

818 48], and 1%, anticipated to be achievable by the time of the experiments. This assumption  
 819 aligns with that of Ref. [42]. A 1% and 3% uncertainty in the cross-section correspond  
 820 to measurement uncertainties in the top quark mass of 8 MeV and 24 MeV, respectively,  
 821 which are comparable to the level of the statistical uncertainty and three times larger than  
 822 it. For details of other uncertainties considered in the list, please find them in Ref. [46].

823 All these estimations are based on the CEPC setup with the latest detector design,  
 824 using a b-tagging efficiency of about 90% and a lepton identification efficiency of about  
 825 66%, which are the leading factors in determining the overall acceptance. The semi-  
 826 leptonic and full hadronic channels of  $t\bar{t}$  are studied. Their corresponding acceptance  $\times$   
 827 efficiencies are 44% and 62%, respectively. In terms of the beam parameters, the beam  
 828 energy could vary 2.6 MeV as estimated from the accelerator team. This impacts the  
 829 measurement of top quark mass maximally by 2 MeV, below the statistical uncertainty,  
 830 consistent with studies in LEP [49, 50] and of ILC [51] that showed small impacts on

831 the top quark measurements in Ref. [42]. The variations on the spread of the luminosity  
 832 spectrum can lead to uncertainties on the top quark mass measurement of 3 MeV and 6  
 833 MeV, if 10% and 20% are considered, respectively. These are quite different than the CLIC  
 834 scenario in Ref. [42] given the different controls of the luminosity spectrum in circular  
 835 and linear colliders.

## 836 15.2.9 $W$ fusion cross section

837 The Higgs width is crucial for determining the absolute value of couplings to Higgs,  
 838 making it essential for testing the electroweak symmetry breaking (EWSB) mechanism.  
 839 A model-independent measurement of the Higgs decay width provides an inclusive test of  
 840 EWSB and imposes constraints on beyond-Standard-Model (BSM) scenarios.

841 Currently, the only experimental measurements of Higgs properties come from the  
 842 LHC. While the Standard Model (SM) predicts a Higgs width of only a few MeV, on-shell  
 843 direct measurements at the LHC can only set an upper limit of a few GeV. Off-shell data,  
 844 however, allows tighter constraints at the level of tens of MeV. Assuming the Higgs width  
 845 equals the sum of partial widths for detectable decay channels, percentage-level precision  
 846 can be achieved. However, this approach is unsuitable for EWSB tests or BSM physics  
 847 due to its *a priori* assumptions.

848 Future lepton colliders, such as the proposed Circular Electron-Positron Collider  
 849 (CEPC), will enable Higgs width measurements at the percentage level. The CEPC is  
 850 expected to operate at two energy stages:

- 851 • 240 GeV with an integrated luminosity of  $20 \text{ ab}^{-1}$ ,
- 852 • 360 GeV with  $1 \text{ ab}^{-1}$ .

853 At 360 GeV, the  $ZH$  production cross-section is 36% lower than at 240 GeV, while  
 854  $WW$  and  $ZZ$  fusion Higgs production cross-sections increase by factors of 3.8 and  
 855 4.6, respectively. These channels are critical for Higgs width determination. While the  
 856 240 GeV data alone provides excellent precision, the 360 GeV run offers an independent  
 857 measurement. The combined precision of the Higgs width determination with the two  
 858 runs can reach a remarkable precision.

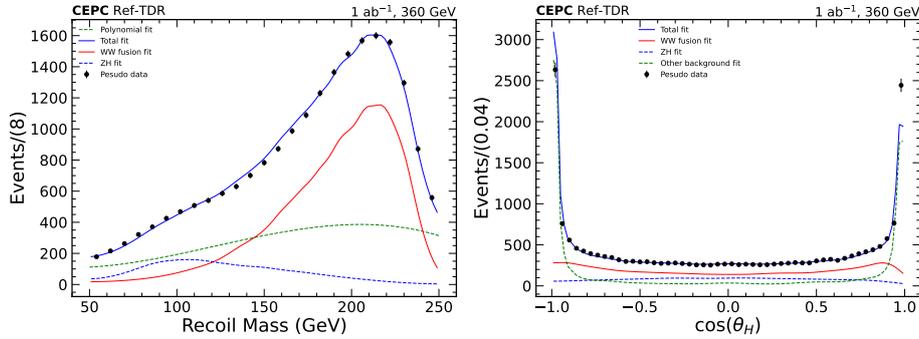

859 The visible final states of signal are a pair of b jets. The main backgrounds is  
 860  $ZH \rightarrow \nu\bar{\nu}b\bar{b}$ . They have same final states and similar distribution in phase space. For  
 861 the SM backgrounds. The 2 fermions backgrounds qq are the major backgrounds, due to  
 862 its large cross-section. Then the irreducible backgrounds including  $ZZ$ ,  $SZ$  are also the  
 863 major backgrounds. The  $WW$  and  $SW$  which visible final states are a pair of jets plus  
 864 one charged lepton are also needed to be considered. Backgrounds can be determined  
 865 very well in theory and experiments, except the interference between the  $ZH$  and the  
 866  $WW$  which is difficult to be generated. It can be extracted by subtracting  $ZH$  and  $WW$   
 867 contributions from the inclusive  $\nu\bar{\nu}H(H \rightarrow b\bar{b})$  sample.

868 Table 15.16 shows the cut flow for signals and backgrounds. Signal and ZH processes  
 869 retain  $\geq 50\%$  efficiency after cuts, while 2-fermion backgrounds are suppressed to  $0.2\%$ .  
 870 Other backgrounds become negligible.

**Table 15.16:** Cut flow for signal and background processes.

Process	$WW$	$ZH$	$qq$	$SW$	$WW$	$SZ$	$ZZ$
Pre-selection	17209	4930	2123258	117427	1686000	178340	266300
$30 < \text{NPFO} < 180$	17196	4927	2103067	117105	1674708	172670	262188
$100 \text{ GeV} < E < 250 \text{ GeV}$	16667	4860	1501935	44023	468516	171306	151500
$p_T > 10 \text{ GeV}$	16272	4847	249395	43119	456289	148885	145116
Lep-veto	15751	4611	245141	16366	187787	147061	141445
$100 \text{ GeV} < m_{\text{total}} < 150 \text{ GeV}$	14291	4055	62897	6744	47649	21893	24613
$50 \text{ GeV} < m_{\text{recoil}} < 250 \text{ GeV}$	14092	3765	40763	3674	26876	16802	14198
$y_{12} > 0.10$	12982	3030	33885	1707	12636	13114	9297
$-0.99 < \cos\theta_{ij} < 0.25$	12742	2789	25714	1368	8154	10489	5658
$b$ -tag	11499	2517	4650	13	78	1897	1023

871 The signal strength is determined by fitting the recoil mass, recoil angle, or both.  
 872 Figure 15.28 shows fitting results with precisions of 2.9% (recoil mass) and 4.5% (recoil  
 873 angle).

**Figure 15.28:** Fitting to the Asimov data on recoil mass (left) and recoil angle (right)

## 874 15.2.10 Long-lived particles

875 The hypothesis that BSM particles could possess long lifetimes, evading detection,  
 876 has transitioned from a nascent idea to a widely accepted and vigorously pursued avenue  
 877 within the physics community. These particles, often called long-lived particles (LLPs),  
 878 serve as sensitive probes into BSM physics. The Higgs boson production via  $e^+e^- \rightarrow ZH$   
 879 at these colliders offers a clean channel to explore rare LLP decays, benefiting from well-  
 880 defined initial states and reduced backgrounds compared to hadron colliders.

881 The Higgs particle can decay into LLPs ( $X$ ) via two decay modes with two jets or  
 882 leptons. In the lepton scenario, such as the  $H \rightarrow XX \rightarrow \text{lepton}$ . The decay of LLPs can

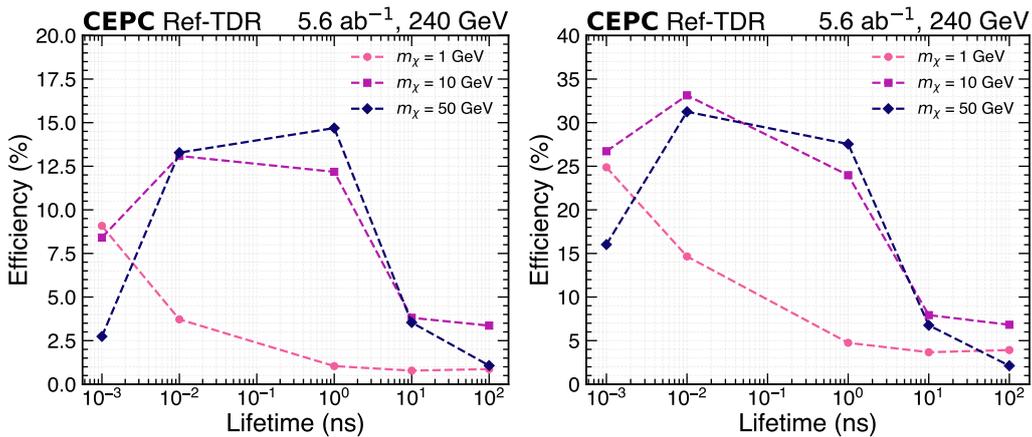

yield either a 2-lepton or a 4-lepton final state, depending on the specific LLP decay model. In this study, we focus on the 2-lepton channel, which includes both dielectron ( $2e$ ) and dimuon ( $2\mu$ ) final states. The distinctive signature is a displaced vertex accompanied by two leptons. We generated 15 signal samples covering the regions of the LLP parameter space, with masses of 1, 10, and 50 GeV and lifetimes ranging from 0.001 ns to 100 ns. The dominant background processes include ZH production, 2-fermion processes with electrons or muons, and 4-fermion processes such as  $ee \rightarrow ZZ \rightarrow ll\nu\nu$ .

This analysis utilizes the tracking and lepton ID performance of the CEPC detector. The events are selected by the lepton pairs after particle ID with momentum larger than 3 GeV. After the selection of  $N_{\text{PFOs}} < 20$  to remove the jets, following selections are applied to suppress background:

- $\Delta\theta$  cut: the difference in theta plane.
- Z veto: mass window cut with  $|M_{ll} - 90| < 10$  GeV.
- $M_{recoil}$ : the recoil mass of the lepton pairs.
- $\Delta T_j = \Sigma(t_{\text{hit},i} - r_{\text{hit},i}/c)$ : the minimal time difference, where  $t_{\text{hit},i}$  represents the hitting time of the  $i^{\text{th}}$  hit in the TOF detector and  $r_{\text{hit},i}$  is the  $i^{\text{th}}$  Euclidean distance to IP, and  $c$  the light speed in vacuum.

The detailed cuts are optimized according to the mass of LLPs, the 2 channels are further selected in below:

- The  $2\mu$  channel: events should only have a muon pair in opposite charge passing the best muon ID WP. After the Z-veto and recoiled mass cut  $M_{recoil} < 140$  GeV. The  $\Delta\theta_{\mu\mu} < 50$  (20) degree and the  $\Delta T_j > 0.15$  (0.1) for  $m_\chi = 10, 50$  (1) GeV.
- The  $2e$  channel: same as the selection criteria of the  $2\mu$  channel except the lepton ID, and  $\Delta T$ . The  $\Delta T_j > 0.05$  (0.01) for  $m_\chi = 10, 50$  (1) GeV.

**Figure 15.29:** The signal efficiency of the LLPs with different lifetime in  $2\mu$  channel (left plot) and  $2e$  channel (right plot).

The Figure 15.29 shows the result of the signal efficiency after event selection. The signal efficiency reaches 12% in  $2\mu$  channel and 30% in  $2e$  channel when  $m_\chi = 10$  GeV.

909 The backgrounds efficiency are shown in the table. For the jet scenario, such as  $H \rightarrow$   
 910  $XX \rightarrow$  jets process, the study using machine learning method is presented in [52], with  
 911 the signal efficiency up to 99% with nearly background free assumption.

## 912 15.2.11 Supersymmetric muon

913 The Supersymmetrized Standard Models (SSMs) bring many appealing features,  
 914 including gauge coupling unification, and dynamical electroweak symmetry breaking,  
 915 and provide a comprehensive theory framework for novel phenomena. For example, the  
 916 Lightest Supersymmetric Particle (LSP) can serve as a viable dark matter (DM) candidate  
 917 with R-parity conservation.

918 As designed for lower energy, CEPC can cover important parameter spaces at low  
 919 mass region, especially at very compressed mass region that is difficult for a high-energy  
 920  $pp$  collider to reach. Light smuon particle is interesting to search for at the CEPC, which  
 921 favored by SUSY explanations to dark matter relic density requirements. This analysis [53]  
 922 will focus on the charged smuon pair production with subsequent decay into a final state  
 923 with two-muon and missing energy from two  $\tilde{\chi}_1^0$ , which is LSP. This analysis can also  
 924 check the muon and missing energy performance from corresponding sub-detectors, such  
 925 as muon detector and calorimeter etc.

926 Events containing exactly two opposite sign (OS) muons with energies above 1.0 GeV are  
 927 selected. The recoil system consists of all the particles except the two OS charged lep-  
 928 tons, which including invisible particles such as neutrinos and neutralinos. The following  
 929 variables are efficient in discriminating the signal events from SM backgrounds:

- 930 •  $\Delta R(\mu, \text{recoil})^1$ , the angular distance between one muon and the recoil system.
- 931 •  $E_\mu$ , the energy of one muon.
- 932 •  $M_{\mu\mu}$ , the invariant mass of two muons.
- 933 •  $M_{\text{recoil}}$ , the invariant mass of the recoil system.

934 The signal regions are defined using the above kinematics selection criteria. To  
 935 estimate the sensitivity of the signals, the median significance is used, which can provide a  
 936 much better approximation to the true significance in regions where the number of signal  
 937 events is not negligible, denoted here by  $Zn$  [54]. The statistical uncertainty and 5% flat  
 938 systematic uncertainty are considered in the  $Zn$  calculation.

939 Three signal regions (SRs) are developed to cover different mass splitting between  $\tilde{\mu}$   
 940 and  $\tilde{\chi}_1^0$  ( $\Delta M$ ). The SR- $\Delta M^h$  covers the region with high  $\Delta M$ , the SR- $\Delta M^m$  covers the  
 941 region with medium  $\Delta M$ , and the SR- $\Delta M^l$  covers the region with low  $\Delta M$ . To improve  
 942 the signal sensitivity, SR- $\Delta M^h$  and SR- $\Delta M^m$  signal regions are divided in  $E_{\mu 1,2}$  intervals.  
 943 The signal regions definition is summarized in Table 15.17. The  $E_\mu$  selections are required

---

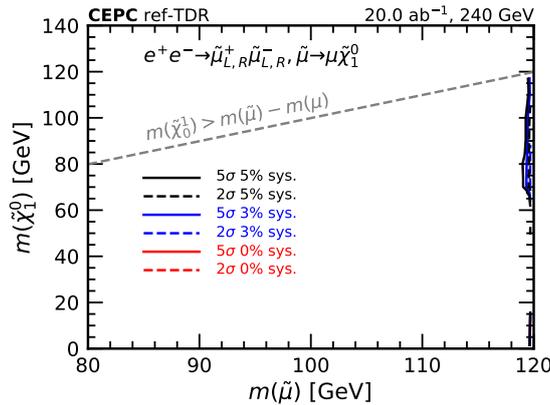

<sup>1</sup> $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ , where  $\eta$  is the pseudorapidity which defined in terms of the polar angle  $\theta$  by  $\eta = -\ln \tan(\theta/2)$  and  $\phi$  is the azimuthal angle.

944 to reject  $\tau\tau$  and  $Z\nu$  processes. The cuts on  $\Delta R(\mu, \text{recoil})$  are used to suppress  $\tau\tau$ ,  $\mu\mu$   
 945 and  $ZZ$  processes, and the cuts on the  $M_{\mu\mu}$  are used to suppress  $WW$  and  $\mu\mu$  processes  
 946 and other backgrounds including  $Z$ . According to the signal topology, most of the signal  
 947 events have large recoil mass. So, a lower cut of the invariant mass of recoil system,  
 948  $M_{\text{recoil}}$ , has been used to reject  $\mu\mu$  and  $Z$  or  $W$  mixing processes and some other SM  
 949 processes without large recoil mass. The main background contributions in the SRs are  
 950 from  $ZZ$  or  $WW \rightarrow \mu\mu\nu\nu$ ,  $\mu\mu$ ,  $WW \rightarrow \ell\ell\nu\nu$ ,  $ZZ \rightarrow \mu\mu\nu\nu$ ,  $\tau\tau$ ,  $ZZ$  or  $WW \rightarrow \tau\tau\nu\nu$   
 951 and  $\nu Z$ ,  $Z \rightarrow \tau\tau$  processes.

SR- $\Delta M^h$	SR- $\Delta M^m$	SR- $\Delta M^l$
$E_{\mu 1,2} > 40 \text{ GeV}$	$9 < E_{\mu 1,2} < 48 \text{ GeV}$	–
$E_{\mu 1,2} \in (40 - 50, > 50) \text{ GeV}$	$E_{\mu 1,2} \in (9 - 25, 25 - 48) \text{ GeV}$	–
$\Delta R(\mu, \text{recoil}) < 2.9$	$1.5 < \Delta R(\mu, \text{recoil}) < 2.8$	–
$M_{\mu\mu} < 60 \text{ GeV}$	$M_{\mu\mu} < 80 \text{ GeV}$	–
$M_{\text{recoil}} > 40 \text{ GeV}$	–	$M_{\text{recoil}} > 220 \text{ GeV}$

**Table 15.17:** Summary of selection requirements for the direct smuon production signal region.  $\Delta M$  means difference of mass between  $\tilde{\mu}$  and  $\tilde{\chi}_1^0$ .

952 The expected sensitivities as function of  $\tilde{\mu}$  mass and  $\tilde{\chi}_1^0$  mass for the signal regions  
 953 with systematic uncertainty of 0 – 5% for direct smuon production are shown in Figure  
 954 15.30. For each signal point, the signal region with best  $Zn$  has been chosen. With  
 955 the assumption of 5% flat systematic uncertainty, the discovery sensitivity can reach up  
 956 to 119 GeV depending on different LSP mass with smuon mass, which is not too much  
 957 effected by systematic uncertainty of detectors.

**Figure 15.30:** The prospected exclusion contours and discovery contours at CEPC for the direct  $\tilde{\mu}$  production with 0 - 5% flat systematic uncertainty.

## 958 **15.2.12 $A_{FB}^\mu (e^+e^- \rightarrow \mu^+\mu^-)$ at $Z$ pole**

959 The CEPC data at  $Z$  pole energy allow high precision electroweak measurements  
 960 of the  $Z$  boson properties, such as the forward-backward charge asymmetry ( $A_{FB}$ ) as a  
 961 function of the effective weak mixing angle. The  $\mu^+\mu^-$  channel is one of the cleanest  
 962 final state at  $Z$  pole. The physics analysis benchmark in this channel offers the simplest  
 963 verification of the detector acceptance, reconstruction of particle-flow objects (PFO), and  
 964 identification of muons. Hence, the measurement of  $A_{FB}$  with the  $e^+e^- \rightarrow \mu^+\mu^-$  process  
 965 is a good example of the physics analyses. The forward-backward asymmetry is defined in  
 966 terms of the angle  $\theta_{CM}$  between the negatively charged final-state muon and the initial-state  
 967 electron in the di-lepton center-of-mass frame.

$$A_{FB} = \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B} \quad (15.6)$$

968 where  $\sigma_F$  ( $\sigma_B$ ) is the total cross section for forward (backward) events, defined by  
 969  $\cos \theta_{CM} > 0$  ( $< 0$ ).  $\theta_{CM}$  is the  $\theta_{\mu^-}$  recomputed at the center-of-mass frame of the di-  
 970 lepton system. The sign of  $\theta_{CM}$  is defined so that  $\cos \theta_{CM} = 1$  events are those in which  
 971 the negatively charged final-state lepton is traveling in the same direction as the incident  
 972 electron.

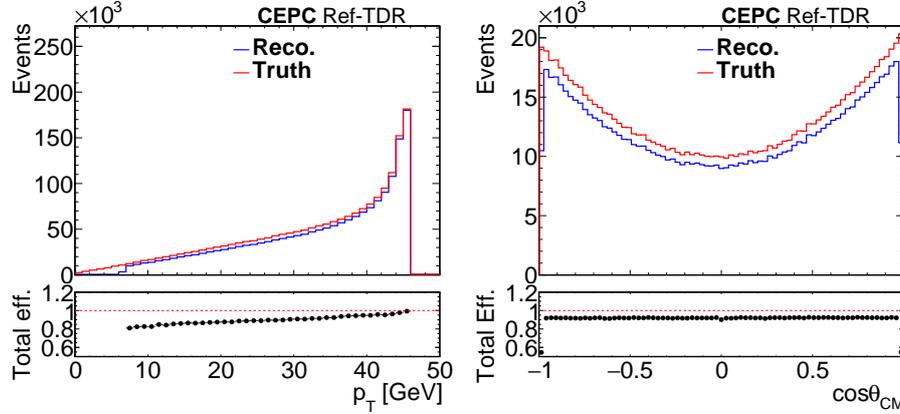

973 When the collision energy is close to the  $Z$  boson mass peak,  $A_{FB}$  reflects pure  $Z$   
 974 exchange and is close to zero because of the small value of the charged-lepton vector  
 975 coupling to  $Z$  bosons. The combination of LEP measurement yields a value of  $A_{FB}^\mu =$   
 976  $0.0163 \pm 0.0014$  in the  $\mu^+\mu^-$  channel. At CEPC, the statistical uncertainty of  $A_{FB}^\mu$  can  
 977 be significantly reduced, the major contributions to the total uncertainty are expected to  
 978 come from systematic sources, such as the energy spread uncertainty, and the energy and  
 979 angular resolution of the reconstructed PFO.

980 The signal and background events are simulated with Whizard+Pythia at LO. The  
 981  $W$  and  $Z$  boson mass (width) values are set precisely to their latest measured values of  
 982 80.377 (2.085) and 91.1876 (2.4952) GeV. The interference between  $Z$  and  $\gamma^*$  has been  
 983 included, and the initial-state-radiation (ISR) and final-state-radiation (FSR) are on in the  
 984 simulation. The predicted  $A_{FB}^\mu$  is  $0.0161 \pm 0.0010$  by simulating 1 million events, which  
 985 is consistent with the LEP result.

986 The  $e^+e^- \rightarrow \mu^+\mu^-$  events are selected by identifying opposite-charge muon pairs.  
 987 The muons are required to pass  $p_T > 1$  GeV,  $\cos \theta < 0.99$ , and the muon identification  
 988 requirements (the "Best" working point). A  $\pm 10$  GeV  $Z$  mass window is required to reject  
 989 the background with genuine muons, which are mainly  $e^+e^- \rightarrow \tau^+\tau^-$  and  $e^+e^- \rightarrow b\bar{b}$   
 990 events. Finally a  $|\cos(\theta_{\mu^-})| > 0.05$  cut is applied to remove the migrations between  
 991 forward and backward regions.

992 Figure 15.31 presents the  $p_T$  and  $\cos(\theta_{CM})$  distributions of the genuine and recon-

993 structured  $\mu^-$ , the ratio pads show the total event selection efficiency.

**Figure 15.31:** (Left) The distribution of  $\mu^- p_T$  at the lab frame. (Right) The distribution of  $\mu^- \cos(\theta_{CM})$  at the center-of-mass frame. The ratio pads show the total event selection efficiency.

994 Table 15.18 shows the selection efficiencies of signal and background. The signal  
 995 efficiency is around 90%, while the background efficiencies are lower than 0.005%, the  
 996 main background is  $e^+e^- \rightarrow \tau^+\tau^-$ , and other backgrounds are negligible.

**Table 15.18:** The cross-section, number of simulated events, and selection efficiencies of signal,  $e^+e^- \rightarrow \mu^+\mu^-$ , and background,  $e^+e^- \rightarrow \tau^+\tau^-$  and  $e^+e^- \rightarrow b\bar{b}$ .

	$e^+e^- \rightarrow \mu^+\mu^-$	$e^+e^- \rightarrow \tau^+\tau^-$	$e^+e^- \rightarrow b\bar{b}$	$e^+e^- \rightarrow e^+e^-$
Cross-section	1.2 nb	1.2 nb	6.6 nb	1.2 nb
Simulated events	982476	185855	44550	32397
A pair of muons	967262	5135	1035	0
$Z$ mass window	903640	5	0	0
Muon $ \cos(\theta)  > 0.05$	869450 (88.5%)	5 (0.003%)	0 (<0.002%)	0 (<0.003%)

997 Since the fraction of signal events is close to 100% after the event selection, the  $A_{FB}^\mu$   
 998 is directly calculated by counting the forward (backward) events, by judging  $\cos(\theta_{CM}) >$   
 999  $0 (< 0)$ . The  $A_{FB}$  calculated in the signal region,  $A_{FB}^{obs}$ , is in a particular phase space, it  
 1000 is usually larger than the  $A_{FB}$  in SM because of the  $Z$  mass window cut. The  $A_{FB}^{obs}$  will  
 1001 be corrected back to the full phase space with the MC samples to get the final result of  
 1002  $A_{FB}^\mu$ . Table 15.19 shows the number of forward (backward) events and the corresponding  
 1003  $A_{FB}^\mu$ , from simulation and after reconstruction. The measured value of  $A_{FB}^\mu$  has  $9 \times 10^{-6}$   
 1004 difference compared to the simulated value, which is taken as one systematic variation.

1005 The statistical uncertainty of  $A_{FB}^\mu$  is extrapolated from  $10^6$  muon pairs in the simulated  
 1006 sample, to two assumptions:

- 1007 • Nominal result: extrapolating to  $1.35 \times 10^9$  muon pairs expected during the one-  
 1008 month low-luminosity  $Z$  running in the first year of  $ZH$  operation, the statistical  
 1009 uncertainty of  $A_{FB}^\mu$  in this case is  $3.1 \times 10^{-5}$ .

- Alternative: extrapolating to  $1.38 \times 10^{11}$  muon pairs expected during 2 years of  $Z$  pole data taking, the statistical uncertainty is  $3 \times 10^{-6}$ .

**Table 15.19:** The number of forward (backward) events and the corresponding  $A_{FB}^\mu$ , from simulation, after selection, and after reconstruction.

	MC particles wo selections	after selections	Using PFO
Forward ( $\cos(\theta_{CM}) > 0$ )	499136	442727	442723
Backward ( $\cos(\theta_{CM}) < 0$ )	483340	426723	426727
$A_{FB}^\mu$ or $A_{FB}^{obs}$	0.016078	0.018407	0.018398
Corrected $A_{FB}^\mu$			0.016070

Several systematic uncertainty sources are considered and their estimation is described below:

- Uncertainty from object mis-identification of the muon: the probability and impact of selecting wrong pairs of PFO from the signal events was found negligible.
- Uncertainty from background: by comparing the  $A_{FB}^{obs}$  with / wo background events, the uncertainty is measured to be  $1 \times 10^{-6}$ .
- Uncertainty from the detector acceptance and resolution of  $|\cos(\theta_{\mu^-})|$  and  $p_T^{\mu^-}$ : apply event selections on the MC particles instead of PFO, and compare the results. This uncertainty is estimated to be  $9 \times 10^{-6}$ .
- Uncertainty from energy spread:  $A_{FB}^\mu$  varies as a function of center-of-mass energy, and according to CEPC accelerator TDR, the beam energy spread at  $Z$  pole is 0.13%. A set of  $e^+e^- \rightarrow \mu^+\mu^-$  samples were simulated at different energy values, and a parameterization of  $A_{FB}^\mu(E_{CM})$  is done. The uncertainty of beam energy spread is estimated by comparing the  $A_{FB}^\mu$  with / wo energy spread, assuming beam energy follows a Gaussian distribution. The uncertainty is measured to be  $2 \times 10^{-5}$ .

An alternative method fitting the  $\cos(\theta_{CM}^{\mu^-})$  distribution was also investigated, the fitting method is treated as a verification of the counting method, and it brings consistent results within the statistical fluctuations of the simulated sample.

Conclusion: this analysis measures the forward-backward asymmetry with  $e^+e^- \rightarrow \mu^+\mu^-$  events at  $Z$  pole ( $A_{FB}^\mu$ ). The uncertainty of measurement is  $\pm 0.000031$  (stat.)  $\pm 0.000022$  (syst.) based on the dataset from the first year of  $ZH$  operation. The CEPC result improves the precision of LEP result ( $\pm 0.0014$ ) by two magnitudes.

## 15.3 Challenges and Plan

### 15.3.1 Strategy for measuring absolute luminosity

Precision measurement of the integrated luminosity  $\mathcal{L}_{int}$  is crucial for the realization of the physics program at CEPC. This is particularly true for the  $Z$ -pole cross-section

1038 measurement, determination of the  $Z$ -width from the line-shape of  $e^+e^- \rightarrow 2f$  pro-  
 1039 duction and the measurements of the  $W$  boson mass and width from the line-shape of  
 1040 the cross-section of  $W$ -pair production near the threshold. At the  $Z$ -pole, the relative  
 1041 uncertainty of  $\mathcal{L}_{\text{int}}$  is required to be of the order of  $10^{-4}$ , while  $10^{-3}$  should suffice at  
 1042 higher center-of-mass energies.

1043 The strategy for achieving the required precision of absolute luminosity measurement  
 1044 involves an iterative process, including the identification of SM processes, monitoring and  
 1045 calibration of detector response, and high-precision calculation.

1046 A compact EM calorimeter has been designed to function as luminometer, as dis-  
 1047 cussed in Section 3.4. Experimental precision of the integrated luminosity is dependent on  
 1048 several sources of uncertainty, including the luminometer's resolution in terms of position  
 1049 and energy measurement of Bhabha showers. The position resolution of Bhabha hits in  
 1050 the luminometer front plane can be improved to a micron level by placing a Si-tracking  
 1051 plane in front of the luminometer, which provides enhanced electron-photon separation.

1052 Uncertainties in  $\mathcal{L}_{\text{int}}$  measurement may arise from various misalignments of the  
 1053 detector arms with respect to each other and the interaction point (IP), as well as from the  
 1054 uncertainties related to finite beam sizes and beam delivery to the IP. These uncertainties  
 1055 collectively referred to as metrological uncertainties, are discussed in Section 3.4. Detailed  
 1056 studies[55] have shown that achieving the targeted precision is feasible at CEPC, both at  
 1057 240 GeV and during the  $Z$ -pole operation. The major challenge at the  $Z$ -pole arises  
 1058 from the need to control the inner aperture of the luminometer at the micron level. A  
 1059 dedicated laser-based system for luminometer position monitoring must be developed,  
 1060 with technologically feasible precision margins set in [55]. Systematic uncertainties in  
 1061 integrated luminosity measurement originating from beam-beam interactions have also  
 1062 been studied [56], showing a comparable impact as at the FCCee [57], and being less  
 1063 pronounced than at linear  $e^+e^-$  colliders due to less compact bunches. The impact of the  
 1064 beam energy spread on  $\mathcal{L}_{\text{int}}$  measurement is discussed in [58], as well as the precision  
 1065 required to determine it from the luminosity spectrum obtained from di-muon production  
 1066 at CEPC. The possibility of using other SM EW processes, such as  $ee \rightarrow \gamma\gamma$ , to determine  
 1067 the luminosity is also under assesment.

1068 For the  $e^+e^- \rightarrow e^+e^-$  process, theoretical uncertainty is limited by the hadronic  
 1069 vacuum polarization at the level of  $10^{-4}$ , while for the  $e^+e^- \rightarrow \gamma\gamma$  process, the contribution  
 1070 of hadronic loops is less than  $10^{-5}$  [59]. The current uncertainty of MC generators for  
 1071 the  $e^+e^- \rightarrow \gamma\gamma$  process is  $10^{-3}$  at  $M_Z$ , for instance, with the BABAYaga NLO [60].  
 1072 When NNLO corrections from [59] are applied, reaching an accuracy of  $\sim 10^{-4}$  could be  
 1073 possible. To achieve an accuracy of  $10^{-4}$  to  $10^{-5}$ , a comprehensive calculation of NNLO  
 1074 QED corrections and, eventually, two-loop weak contributions will be required.

1075 The process of two-photon annihilation of  $e^+e^-$  at energies above the  $Z$  boson mass  
 1076 has been studied at the LEP collider [61]. Each of the four detectors observed approx-

1077 imately 5000 events, indicating that the process was primarily observed with statistical  
1078 uncertainty being dominant. The most accurate result was obtained with the OPAL detec-  
1079 tor [62], where systematic uncertainty reached 0.56%. The major part of this systematic  
1080 uncertainty (0.46%) was related to the photon conversion probability, limited by the avail-  
1081 able statistics of photon events. At CEPC, the conversion probability can be expected to  
1082 be well studied due to the large statistics of photon events.

1083 At CEPC, the process  $e^+e^- \rightarrow \gamma\gamma$  can be utilized for determining luminosity offline,  
1084 provided there is a sufficiently large data set (at least  $3.3 \text{ ab}^{-1}$  is needed to achieve  $10^{-4}$   
1085 accuracy). The advantage of using this process lies in the capability of the main detector to  
1086 determine luminosity, which helps reduce systematic uncertainties in relative luminosity  
1087 measurement. The reduction in systematic uncertainties can be confirmed by comparing  
1088 the ratio of the number of  $\gamma\gamma$  events to  $e^+e^-$  events under consistent selection conditions  
1089 with theoretical predictions.

### 1090 **15.3.2 Application of the resonant depolarization method for the** 1091 **$W/Z$ boson mass determination**

1092 The resonant depolarization technique, which employs a pulsed "depolarizer" with  
1093 frequency-scan capability to induce a narrow artificial spin resonance for beam depolar-  
1094 ization, and measures the location of depolarization with the precisely known depolarizer  
1095 frequency, currently provides the most precise measurements of the beam energy. Its im-  
1096 plementation at the CEPC would require achieving transverse polarization levels of at least  
1097 5% to 10% for both beams. This also necessitates the implementation of laser-Compton  
1098 polarimeters capable of measuring the vertical beam polarization with a resolution of 1%  
1099 every few seconds. Additionally, tracking the evolution of beam energies throughout the  
1100 physics runs is essential for the precision measurements of  $W/Z$  masses. This requires  
1101 conducting resonant depolarization measurements frequently, approximately every 10–15  
1102 minutes, where each measurement will depolarize one or two bunches for each particle  
1103 species and determine the instant beam energy. Interpolation can then be used to model  
1104 the evolution of the beam energies more precisely.

1105 As detailed in the CEPC Accelerator TDR [63] and references therein, besides the  
1106 scheme of using self-polarization in the collider rings [64] which can generate above 10%  
1107 polarization in about 2 hours, particularly with the help of asymmetric wigglers at the  
1108  $Z$ -pole, it is also viable to prepare polarized lepton beams from the source. These beams  
1109 can be transported throughout the injector chain and injected into the collider rings to  
1110 meet the requirements of beam energy calibration. The strategy involves utilizing one  
1111 or two bunches per species that can be efficiently depolarized. Once depolarized, they  
1112 can be readily removed and replaced with new polarized bunches. This process aligns  
1113 with the capabilities of the injector chain, ensuring a streamlined calibration procedure,

1114 and can deliver above 50% polarized electron bunches and above 20% polarized positron  
1115 bunches. Availability studies [65], including failures of systems like RF systems or power  
1116 converters, suggest that the latter approach could promise much less physics dead time  
1117 and a substantial increase in the integrated luminosity.

1118 Note that this approach requires some modification of the entire injector chain as  
1119 outlined in the CEPC Accelerator TDR and should be implemented in an updated design.  
1120 Additionally, preparing electron beams with over 85% polarization from the source is  
1121 achievable with status-of-the-art technology, and this approach has the potential to realize  
1122 over 50% longitudinal polarization for colliding beam experiments. There is a 400 kV  
1123 photocathode DC gun at the Platform of Advanced Photon Source Technology R&D  
1124 (PAPS) managed by IHEP, and there are ongoing efforts to convert it to a polarized electron  
1125 source and build associated beamline to measure the beam polarization, in addition to  
1126 domestic fabrication of the superlattice GaAs/GaAsP photocathodes. The plan is to have  
1127 first experiments of polarized electron beam generation in 2027.

1128 To prepare for the high performance of Compton polarimetry, polarized electron  
1129 sources and resonant depolarization techniques to be used in CEPC, dedicated R&D efforts  
1130 have been underway in the EDR phase of the CEPC. In particular, a Compton polarimeter  
1131 is being constructed at BEPCII, reusing the hutch and beamline of a dismantled wiggler,  
1132 to measure the vertical polarization of the electron beam in the storage ring due to the  
1133 self-polarization build-up. Although this Compton polarimeter is based on detecting  
1134 backscattered  $\gamma$  photons, rather than the preferred solution of detecting backscattered  
1135 electrons as planned for CEPC, it will establish the know-how to operate such a delicate  
1136 instrument, as well as advance laser polarization control and pixel detector technologies  
1137 for Compton polarimetry. The conceptual design of the Compton polarimeter has been  
1138 finalized, and modification of the beamline and the hutch region has been completed. The  
1139 first beam experiment of the Compton polarimeter is underway.

1140 Once reliable beam polarization measurements are achieved, demonstration of beam  
1141 energy calibration with the resonant depolarization technique is foreseen at BEPCII in  
1142 the coming 2-3 years. Being a double-ring collider with many bunches similar to CEPC,  
1143 BEPCII will serve as an ideal test bed for the operational concepts of resonant depolariza-  
1144 tion for CEPC, for example using dedicated pilot bunches for resonant depolarization and  
1145 continuous monitoring of the beam energy throughout physics runs.

1146 The knowledge gained through these R&D activities will set a solid foundation for  
1147 the practical design of Compton polarimetry and preparation for resonant depolarization  
1148 applications at CEPC.

## 1149 **15.3.3 Methods and considerations for Calibration, Alignment**

1150 This section summarizes the calibration and alignment strategies for CEPC subde-  
1151 tectors, combining physics-driven methods and technical monitoring to meet the required  
1152 performance for precision measurements.

1153 **Vertex Detector Calibration and Alignment** Vertex alignment is based on  $Z \rightarrow \mu^+\mu^-$   
1154 events, minimizing track-hit residuals through iterative geometry updates. Sub-10  $\mu\text{m}$   
1155 accuracy is achieved, with impact parameter resolution validated using displaced  $K_S^0 \rightarrow$   
1156  $\pi^+\pi^-$  vertices. Thermal and mechanical shifts are monitored over time, with correction  
1157 maps derived from residual drifts. Temperature variations of  $1^\circ\text{C}$  can induce micron-level  
1158 misalignments. Temporal stability is cross-checked using photon conversions and  $K_S^0$   
1159 events.

1160 Charge collection efficiency is monitored with  $e^+e^-$  pairs from conversions, and  
1161 pixel gain equalization uses MIP tracks to reduce response variation. Inter-layer timing  
1162 alignment is calibrated using relativistic muons, reaching synchronization better than  
1163 0.5 ns. Radiation effects are tracked via MIP signal trends, with all sensors pre-tested for  
1164 long-term stability.

1165 **Tracker Calibration and Alignment** The CEPC tracking system, comprising silicon  
1166 trackers and a TPC, is calibrated for geometry, momentum scale, and timing. Initial  
1167 alignment uses cosmic and beam halo muons to reduce residuals below 10  $\mu\text{m}$  (silicon)  
1168 and 100  $\mu\text{m}$  (TPC).

1169 Momentum calibration employs  $Z$ ,  $J/\psi$ , and  $\Upsilon$  resonances. Deviations in invariant  
1170 mass are used to extract per-module corrections, combined via momentum-weighted  
1171 averages.

1172 OTK and TPC timing is calibrated using tau decay chains and cosmic muons. In  
1173 the TPC, UV laser tracks calibrate drift velocity and correct space charge effects. Timing  
1174 resolution reaches 50 ps for OTK and 100  $\mu\text{m}$  spatial precision for the TPC.

1175 A Kalman filter refines alignment using  $Z \rightarrow \mu^+\mu^-$  events, reducing residuals  
1176 to design-level precision. Real-time monitoring involves tracking channel efficiency and  
1177 making environmental corrections based on both temperature and radiation dose, ensuring  
1178 optimal performance.

1179 Laser interferometry tracks mechanical shifts at micron scale. Structural expansion  
1180 is modeled and combined with track-based alignment to maintain long-term stability.

1181 **ECAL Calibration and Alignment** ECAL calibration is performed using physics-  
1182 driven and monitoring-based methods to ensure an electromagnetic energy resolution  
1183 around  $3\%/\sqrt{E}$ .

1184 The  $E/p$  technique, utilizing electrons from  $e^+e^-$  and  $W/Z$  decays, compares ECAL  
1185 energy to tracker momentum to monitor gain drifts. Corrections are updated regularly  
1186 based on time-dependent  $E/p$  trends.

1187 Intercalibration employs  $\pi^0 \rightarrow \gamma\gamma$  decays, reconstructing invariant masses and  
1188 weighting energy contributions by crystal to derive per-channel constants. Iterative av-  
1189 eraging and  $\eta$ -ring smoothing reduce local statistical fluctuations. The absolute scale is  
1190 determined from  $Z \rightarrow e^+e^-$  events by comparing reconstructed masses to the nominal  $Z$   
1191 mass.  $J/\psi \rightarrow e^+e^-$  decays provide low-energy cross-checks.

1192 Cosmic muons supply continuous monitoring of SiPM gain and transparency changes.  
1193 Timing synchronization between channels is refined using relativistic muons, reaching  
1194 alignment within 0.5 ns.

1195 Track-based ECAL alignment extrapolates high- $p_T$  tracker tracks to the calorimeter  
1196 surface, minimizing residuals to refine module positions. Mechanical stability is monitored  
1197 with strain sensors and laser lines, ensuring long-term alignment consistency.

1198 **HCAL Calibration and Alignment** The HCAL is calibrated to achieve 3–4% jet energy  
1199 resolution at 100 GeV, beginning with radioactive source scans and test beam calibration  
1200 of modules during construction. These define initial channel gains and validate response  
1201 uniformity across  $\eta$  and  $\phi$ .

1202 During operation, gain stability is maintained via LED/laser monitoring. Energy  
1203 reconstruction applies corrections for light yield variation, intercalibration factors, and  
1204  $\eta$ -dependent scaling. Pileup suppression is performed with pulse-shape fits.

1205  $\phi$ -symmetry is exploited to equalize response across  $\eta$  rings, using statistical moment  
1206 methods. The absolute scale is tuned using isolated charged hadrons, comparing HCAL  
1207 energy to tracker momentum after ECAL subtraction. Dijet and multijet events provide  
1208 additional cross-checks via transverse balance and reconstructed  $W/Z$  masses.

1209 SiPM gain and radiation damage are tracked with MIP response and temperature  
1210 modeling. Alignment is derived from cosmic-ray muons traversing multiple layers, with  
1211 geometry updated to minimize hit residuals. Structural sensors ensure sub-mm mechanical  
1212 stability.

1213 **Muon Detector Calibration and Alignment** For the muon system, channel efficiency  
1214 and energy response are calibrated with  $Z \rightarrow \mu^+\mu^-$  tracks, extrapolated from the tracker.  
1215 MIP peaks and detection efficiency are extracted layer-by-layer. Cosmic muons comple-  
1216 ment this with absolute intercalibration, and responses are smoothed over  $\eta$  regions.

1217 Muon ID performance is maintained using likelihood templates based on hit multi-  
1218 plicity and penetration depth, trained on muon and pion control samples. SiPM gain is  
1219 monitored via cosmic MIPs and LED pulses, with corrections applied for temperature-  
1220 induced variation and optical degradation.

1221 Timing calibration uses dual-ended strip readout and waveform fitting, achieving  
1222 sub-ns resolution after correcting propagation delays. Geometry alignment is refined by  
1223 minimizing residuals between extrapolated tracks and measured hits using  $Z$  events and  
1224 cosmics. Embedded mechanical sensors help monitor structural deformation, ensuring  
1225 alignment stability over time.

### 1226 **15.3.4 Further technology decisions and detector optimization**

1227 Given the timing constraint of the current TDR study, there are several areas for  
1228 further optimizations beyond this reference detector TDR results. These areas will be  
1229 considered in the long term:

- 1230 • ECAL Transverse Granularity for Boosted  $\pi^0/\gamma$  Separation

1231 We will evaluate the transverse granularity of the ECAL's long crystal bars to  
1232 improve discrimination between boosted  $\pi^0$  decays and single photons. This study  
1233 will quantify the impact of finer segmentation on reconstruction algorithms and  
1234 photon purity, particularly in high-occupancy regions.

- 1235 • HCAL Thickness vs. Polar Angle for Jet Energy Resolution

1236 A parameterized analysis of HCAL thickness as a function of polar angle will be  
1237 conducted to balance jet energy resolution against cost constraints. This includes  
1238 optimizing the radial and longitudinal segmentation to mitigate energy leakage while  
1239 minimizing cost.

- 1240 • Muon System Optimization for Long-Lived Particle Searches

1241 The muon identification performance will be studied as a function of the number  
1242 of muon detector layers. We will assess trade-offs between layer count, spatial  
1243 coverage, and sensitivity to long-lived particles (e.g. displaced vertices), ensuring  
1244 compatibility with background rejection requirements.

- 1245 • Low-Momentum Charged Hadron PID with AC-LGAD Timing Layers

1246 To enhance the identification of low-momentum charged hadrons, which could not  
1247 reach the Outer Tracker layer, a proposal is made to replace the outermost layer of the  
1248 Inner Tracker with an AC-LGAD-based timing layer. This technology's combined  
1249 spatial ( $\sim 10 \mu\text{m}$ ) and timing ( $\sim 50 \text{ps}$ ) resolution could significantly improve  
1250  $\pi/K/p$  separation without compromising tracking performance.

1251 In terms of technology choices, several key performance-driven evaluations needed  
1252 for detector subsystems include:

- 1253 • Pixel vs. Strip ITK for PID Requirements

1254 A comparative study will assess the impact of using strip-based ITK instead of  
1255 pixel sensors on particle identification (PID) capabilities. This includes evaluating  
1256 resolution trade-offs, occupancy limits, and compatibility with the timing layer  
1257 integration proposed above.

- 1258 • Beam Background and TPC vs. Drift Chamber (DC) at High Luminosity  $Z$  pole  
1259 run  
1260 Beam-induced backgrounds will be simulated to quantify their impact on tracking  
1261 subsystem choices (TPC vs. DC) during high-luminosity  $Z$ -pole running. Critical  
1262 metrics include occupancy, hit reconstruction efficiency, and robustness against  
1263 pileup.
- 1264 • HTS Ultra-Thin Magnet Feasibility  
1265 The potential use of High-Temperature Superconducting (HTS) magnets will be  
1266 explored to reduce the solenoid’s radial thickness while maintaining field strength.  
1267 This study will address mechanical stability, quench protection, and integration with  
1268 the detector’s overall material budget.

## 1269 15.4 Summary

1270 With the reference detector design and full simulation, detailed performance of the  
1271 fundamental objects have been evaluated, and a set of benchmarks have been conducted.  
1272 They illustrate the detector performance for center-of-mass energies in the range from  
1273 91 GeV up to 360 GeV. **All results obtained have been summarized in the following Tables**  
1274 **- to be made.** In addition, areas of challenges and plans beyond the current TDR are also  
1275 identified.
