Conceptual Design Report

Volume II - Physics & Detector

The CEPC Study Group

Fall 2018

Draft: Wednesday 1st August, 2018-03:54

Draft-V0.4

ACKNOWLEDGMENTS

The CEPC Physics and Detector Conceptual Design Report (CDR) was prepared and written by the CEPC Study Group. The study was organised and led by scientists from the Institute of High Energy Physics (IHEP) of the Chinese Academy of Sciences (CAS), and from many universities and other institutes in China and abroad. The study was partially supported ...

CHAPTER 1

EXECUTIVE SUMMARY

This document is the second volume of the Conceptual Design Report (CDR) for the Circular Electron Positron Collider (CEPC) project. This volume summarizes the physics potential of the CEPC, possible detector concepts and the corresponding R&D program. The first volume [?], released in July 2018, describes the CEPC accelerator complex design, the associated civil engineering and strategic alternative scenarios. This CDR follows up on the preliminary Conceptual Design Report (preCDR) study [1], released in 2015, and culminates three years of work since then.

The main purpose of this document is to address the physics potential of a future circular electron positron collider. The CEPC operation will be staged in a few steps of center-of-mass energy to maximize its physics potential. It is expected the CEPC to start operations at 240 GeV, giving raise to a wealth of Higgs physics, and then move to lower center-of-mass energies and collect large samples of W and Z bosons. This complete program of precision standard-model physics will certainly place stringent constraints on new physics, and it has the potential for direct observation of new physics.

This CDR presents the essential features of the detectors that are required to extract the full physics potential of the CEPC. The experimental conditions at high-luminosity high-energy circular electron positron colliders are more challenging than those considered previously for electron-positron linear colliders due to the higher levels of beam-induced backgrounds, and the 25 ns bunch-spacing required to collect extremely large samples of Z boson events. A main goal of this report is to demonstrate that a wide range of high-precision physics measurements can be made at CEPC with detectors that are feasible expanding on the on-going realistic R&D program.

Consequently, part of this report is devoted to understanding the impact of the machine environment on the detector with the aim of demonstrating, with the example of a few

realistic detector concepts, that high-precision physics measurements can be made at the CEPC. This document concentrates on the detector requirements and physics measurements at the highest CEPC center-of-mass energy of 240 GeV, when the beam induced backgrounds are higher, but consideration is also given to the high-rate operation at the Z-boson mass energy.

A pre-release version of this Physics and Detector CDR was reviewed by an international review committee in September 2018. The comments from the reviewers have been taken into account in this final document, and details about it can be found in Appendix [?].

This section is just a placeholder for now. It will be a short introduction 2-4 pages with a very short motivation for the CEPC project [2] and the workings of the CDR. We will define here the goals of the CDR and will already mention the connection between the different detector concepts. We will mention quickly some of the challenges and the future R&D program. We can also provide the short descriptions to the chapters in the CDR. There will be no subsections sections in this text. Each part below will be a short executive summary of the corresponding sections in the text.

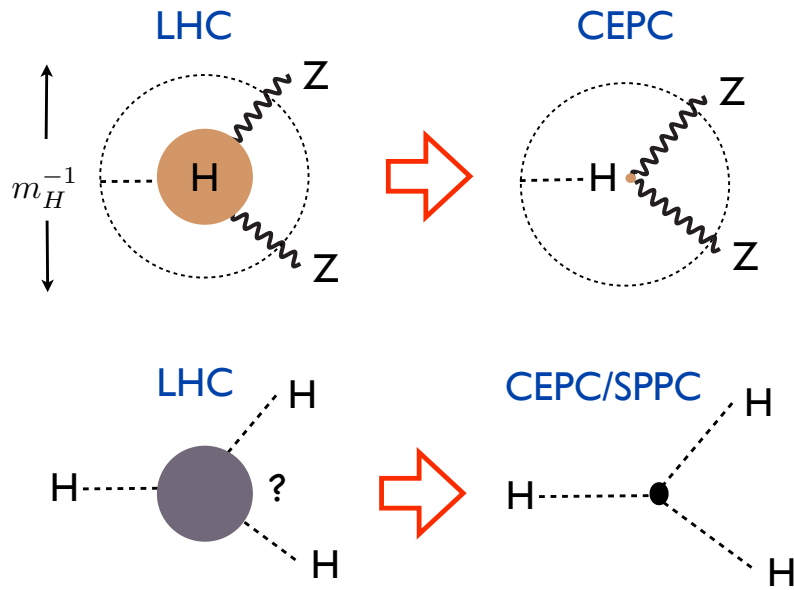

Figure 2.1: A sketch of two of the central goals of the CEPC and SPPC. The CEPC will probe whether the Higgs is truly “elementary”, with a resolution up to a hundred times more powerful than the LHC. The SPPC will see, for the first time, a fundamentally new dynamical process — the self-interaction of an elementary particle — uniquely associated with the Higgs.

CHAPTER 3

CEPC EXPERIMENTAL CONDITIONS, PHYSICS REQUIREMENTS AND DETECTOR CONCEPTS

The CEPC physics program includes the precision test of the Standard Model and the search for new physics over a wide range of center-of-mass energies. It has stringent requirements on the detector performance, including large solid angle coverage, precise track momentum resolution, precise photon energy reconstruction, excellent particle identification, excellent jet reconstruction, high efficiency vertex reconstruction, and jet flavor tagging.

This chapter describes the design requirements for the CEPC detectors to achieve these physics goals, taking into account the CEPC collision environment and the relevant backgrounds. Three preliminary general purpose detector concepts are introduced in this chapter. The baseline detector of the CEPC is guided by the Particle Flow Principle and take reference from the International Large Detector. It uses 3 Tesla solenoid magnetic field and an ultra high granularity calorimeter system. An alternative proposal substitutes the Time Projection Chamber with a full-silicon tracker (FST). A third design based on a lower magnetic field of 2 Tesla, a drift chamber, and a dual readout calorimetry is also presented. The baseline concept detector is used for the physics performance studies in this Conceptual Design Report, the other two designs are considered validated alternatives.

3.1 Experimental conditions

The CEPC can be operated as a Z factory ($\sqrt{s} = 91.2$ GeV) and a Higgs factory ($\sqrt{s} = 240$ GeV). It could also perform W threshold scan at \sqrt{s} around 160 GeV and determines precisely the mass and the width of the W boson. According to the CEPC Accelerator

Operation mode	Z factory	W threshold scan	Higgs factory
\sqrt{s}/GeV	91.2	158 - 172	240
$L/10^{34}\text{cm}^{-2}\text{s}^{-1}$	16-32	10	3
Running time/year	2	1	7
Integrated Luminosity/ ab^{-1}	8 - 16	2.5	5
Higgs yield	-	-	10^6
W yield	-	10^7	10^8
Z yield	10^{11-12}	10^9	10^9

Table 3.1: Instance luminosity at different \sqrt{s} and anticipated boson yields at the CEPC.

CDR [1], the luminosities and the yields of the objective massive particles at these center of mass energies are listed in Table 3.1.

As an electron positron collider, the CEPC is extremely clean comparing to the LHC. Fig. 3.1 shows the cross section of leading SM processes at the electron positron collision. The ratio between the cross sections of the Higgs signal and the inclusive physics events is roughly $10^{-2} \sim 10^{-3}$ at the CEPC [2], eight orders of magnitudes larger than that in the LHC. At the CEPC, the entire physics event rate is so low that every physics event can be recorded, providing ideal samples for the precision measurements.

The beam parameters of different CEPC physics operations are summarized in Tab ?? . The main physics objective and leading physics requirements for the detector/collider system is discussed below.

3.1.1 Higgs Operation

The CEPC Higgs operation is expected to accumulate an integrated luminosity of 5 ab^{-1} and produce 1 million Higgs bosons. Its main physics objective is to determine precisely the Higgs boson properties. The Higgs signal event rate is of the order of 0.01 Hz.

The typical measurements including the absolute measurement of $\sigma(ZH)$ via the recoil mass method, the Higgs event rates measurements, and the differential measurements on the Higgs events.

Combing these measurements leads to a model-independent determination of the Higgs boson decay branching ratio, the couplings between the Higgs boson and its decay final states, and the total Higgs width. These quantities could typically be determined to a relative precision of 0.1% - 1%, one order of magnitude better than the HL-LHC experiments. The differential measurements provide input for the quantum number determination and the coefficient measurements in the Effective Lagrangian Theory framework. In addition, the recoil mass method and the clean collision environment make CEPC an extremely sensitive probe to the Higgs exotic decays. A general exploration shows that the 95% C.L. of the Higgs exotic decays could be limited to the range of per mille level to 10^{-6} [3]. On top of the Higgs events, roughly 100 million W bosons and 1 billion Z bosons will be

Figure 3.2: Main beam parameters for the CEPC operation

generated. These events could be used for both EW precision measurements and in-situ calibration for the detector.

For the Higgs measurement, the integrated luminosity should be measured to a relative accuracy better than 0.1%. To limit the uncertainty on the Higgs mass measurement via the recoil mass spectrum, the beam energy needs to be calibrated to an accuracy of 1 MeV.

3.1.2 Z pole Operation

The total statistic of the Z pole statistics would be 5 orders of magnitude higher than that of the LEP. In fact, the CEPC could produce the entire LEP I data sample in 5 minutes. From which, electroweak observables such as $A_{FB}^{0,b}$, R_b , and those measured with the Z line shape can be determined. In addition, the Z pole data also provide huge good access for the flavor physics.

At 91.2 GeV center of mass energy, the leading physics process is the $Z \rightarrow \text{fermion}$ events, plus a small fraction of the $\gamma\gamma$ background and the Bhabha events. These events have so clean signature that it's easy to distinguish them from each other. However, given the extremely small statistic uncertainty, the understanding and calibration of the misidentifications between different physics events are essential.

Being the weak interaction mediator, the Z boson decays into all kinds of the SM fermions except the top quark. In order to distinguish different Z boson decay modes, a high efficiency, high purity identification of leptons, taus, and jets, are highly appreciated. The precise energy-momentum reconstruction, especially the good angular resolution for these physics objects, are crucial for the Z pole physics measurements such as A_{FB}^μ and the weak mixing angle. To determine precisely the measurements associated with the b-jets, a precise reconstruction of the jet flavor and the jet charge is crucial.

In order to extract precisely the Z line shape information, the beam energy needs to be calibrated to an accuracy better than MeV, and the luminosity is required to be controlled to a relative accuracy of 10^{-4} .

The CEPC Z pole operation provides a large statistic of $Z \rightarrow \tau^+\tau^-$ sample. Many photons are generated in the π^0 s from the τ decay and it's crucial to identify these individual photons. In other words, the CEPC detector should provide good separation performance and count precisely how many photons (π^0 s) are generated in the $Z \rightarrow \tau^+\tau^-$ events. As for the flavor physics measurement, the identification of the charged kaon is essential.

3.1.3 W threshold scan

At the W threshold scan, the CEPC could produce 10^7 WW event in a year. The W threshold scan is mainly devoting to the W boson mass and W boson width measurements. In addition, it provides input for the TGC measurements.

A precise determination of the beam energy is indispensable for the W threshold scan. Typically, the beam energy needs to be calibrated to sub-MeV level accuracy.

The EW and the Higgs measurements provide complementary information, and a combination significantly enhances the physics reach [4] [5]. The dedicated physics requirements for the CEPC physics program are summarized below.

3.2 Physics Requirements

As a tremendous Higgs, Z, and W boson factory, the CEPC should be equipped with detectors that can identify all the corresponding physics objects with high efficiency, high purity and measure them with high precision. In addition, the CEPC physics program requires a precise determination of the instant luminosity, a precise control and monitoring of the beam energy. Generally, the CEPC detector is required to:

- 1, Be adequate to the CEPC collision environment: the detector should be fast enough to record all the physics events and robust enough against the irradiation.
- 2, Highly hermetic. The detector should provide a solid angle coverage of $|\cos(\theta)| < 0.99$.
- 3, The luminosity should be measured to a relative accuracy of 0.1% for the Higgs operation, and 10^{-4} for the Z line shape scan.
- 4, The beam energy should be measured to an accuracy of the order of 1 MeV for the Higgs operation, and 100 keV for the Z pole and W mass threshold scan.

The requirements on the physics objects reconstruction are briefly quantified with benchmark physics analyses, see discussion below.

3.2.1 Multiplicity

In each physics events, the visible final state particles include the charged particles, the photons, and the neutral hadrons. The multiplicities of these three basic ingredients for the WW, ZZ, and ZH processes (the leading SM processes) at the CEPC Higgs operation is shown in Fig. 3.3.

The charged tracks and the photons carry most of the visible energies and are much numerous than the neutral hadrons. They follow a similar distribution of multiplicity, which can be as high as $\mathcal{O}(10^2)$. These final state particles can have extremely small angles in between, especially for those generated in the high energy jets. A efficient separation of these final state particles provides a solid basis for the reconstruction of all the physics objects, which is addressed explicitly by the Particle Flow Principle.

3.2.2 Tracking

The CEPC detector should have excellent track finding efficiency and track momentum resolution. Corresponding to the WW, ZZ and the ZH processes at the CEPC Higgs operation, the energy and polar angle distributions of the charged particles are shown in Fig. 3.4.

In the polar angle distribution, the ZH process is almost flat in the polar angle direction, while the other two processes are more forward region dominated. A large solid angle coverage is essential to characterize and to distinguish different physics processes, and a typical coverage of $|\cos(\theta)| = 0.99$ is benchmarked. In the energy distribution, these three processes shares the same pattern. For energy below 20 GeV, these distributions follow an exponential distribution, while in the high energy side there is a flat plateau with a steep

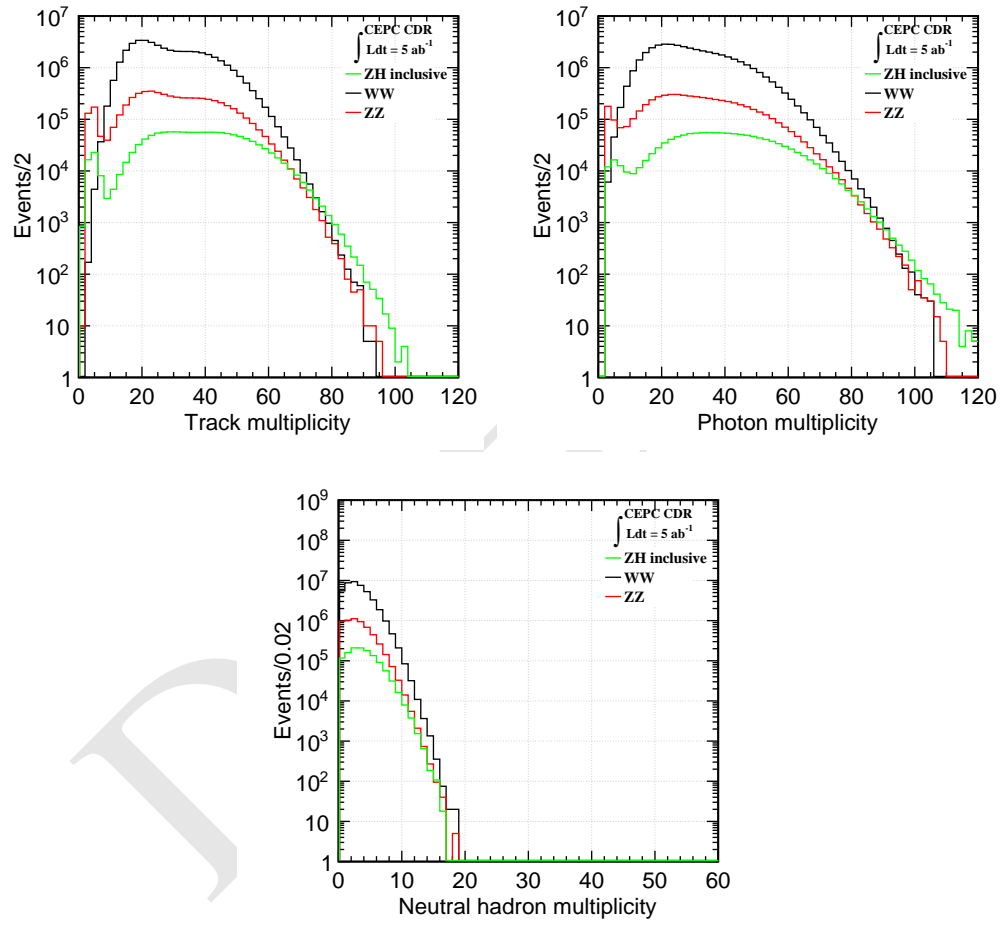

Figure 3.3: The multiplicity of charged particle, photons, and neutral hadrons at the leading physics processes at the CEPC Higgs operation, normalized to 5 ab^{-1} nominal integrated luminosity.

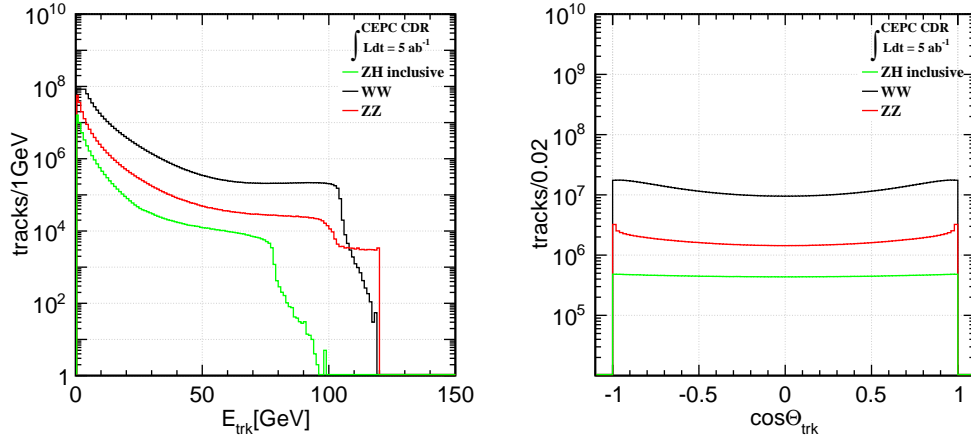

Figure 3.4: Energy and polar angle distribution of charged particles at the leading physics processes at the CEPC Higgs operation, normalized to 5 ab^{-1} nominal integrated luminosity.

cliff. Therefore, the CEPC detector should have a high efficiency track reconstruction, especially for these low energy tracks. Meanwhile, it should have an excellent momentum resolution and linearity for a wide energy range (0.1 - 120 GeV).

For any tracks within the detector acceptance and an transverse momentum larger than 1 GeV, we request an track finding efficiency better than 99%. In order to measure the $H \rightarrow \mu^+ \mu^-$ signal and to reconstruct precisely the Higgs boson mass from the recoil mass distribution at $l^+ l^- H$ events, the momentum resolution is required to achieve a per mille level relative accuracy.

3.2.3 Lepton

The lepton is one of the most important physics signatures and it plays a crucial role in the classification of different physics events. A high efficiency and high purity lepton identification is fundamental for the CEPC physics program.

At the CEPC Higgs operation, roughly 7% of the Higgs bosons are generated with a pair of leptons. These $l^+ l^- H$ samples are the golden signal for the Higgs recoil mass analyses. Fig. 3.5 shows the energy distribution of the prompt leptons and these generated in Higgs decay cascade. The prompt muons at the $\mu^+ \mu^- H$ events has a flat energy distribution within the kinematic allowance (20 - 100 GeV) and a low energy tail induced by the Z boson width and the Final State Radiation (FSR).

The prompt electron-positron at the $e^+ e^- H$ events follows a similar pattern, except the population increases at energy smaller than 10 GeV. These low-energy peak is mainly induced by the Z fusion events.

The Higgs decay also generates leptons, which is mostly concentrated in the low energy side, but can have energies as high as 70 GeV. These high energy leptons are mainly generated from $H \rightarrow \tau^+ \tau^-$, ZZ^* , WW^* decay cascades.

The basic requirements on the lepton identification for the CEPC detector is, to identify the prompt leptons with high efficiency and high purity. Therefore, we require a lepton identification with efficiency higher than 99% and misidentification rate smaller than 2% for energetic isolated leptons (energetic means energy higher than 5 GeV). These

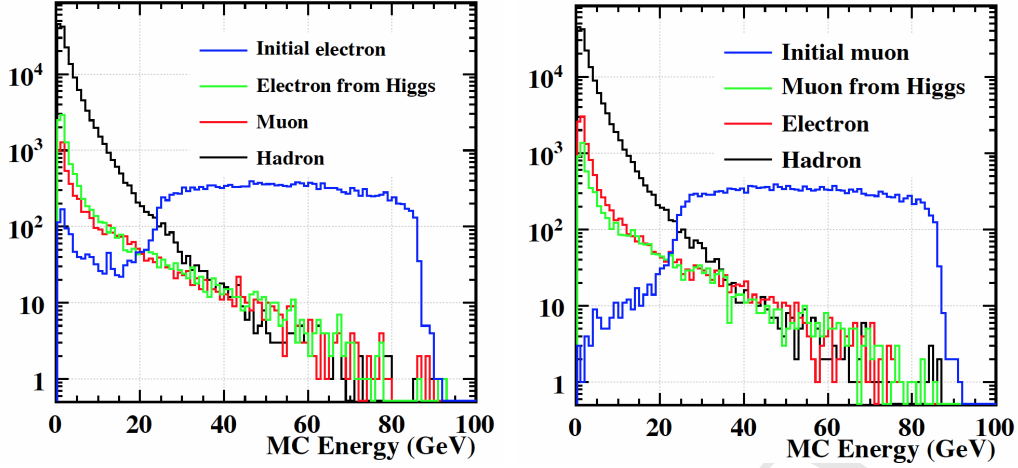

Figure 3.5: Energy spectrum of the leptons and the charged hadrons in the e^+e^-H events (left) and the $\mu^+\mu^-H$ events (right).

requirement is also essential for the identification of $H \rightarrow \tau^+\tau^-$ events and the semi-leptonic/leptonic decays modes of $H \rightarrow ZZ^*, WW^*$ events.

The numerous jet leptons generated in the Higgs decay cascades can be crucial for the jet flavor tagging and jet charge reconstruction. Therefore, a good identification of these jet leptons is highly appreciated. More detailed study is needed to quantify the requirements on the jet lepton identification.

3.2.4 Particle identification

The particle identification, especially the identification of charged kaons, is crucial for the flavor physics. Similar to the jet leptons, the identification of charged kaon is highly appreciated for the jet flavor tagging and jet charge reconstruction. Typically, we request the efficiency and purity of the kaon identification at the inclusive Z pole sample to be better than 90%.

3.2.5 Photons

The photons is crucial for the jet energy resolution, the $H \rightarrow \gamma\gamma$ branching ratio measurements, and the physics with τ final states. Fig. 3.7 shows the energy and polar angle distribution for the inclusive photons, and the ISR photons, from these benchmark physics processes at the CEPC Higgs operation.

As for the photon reconstruction, we request a photon identification efficiency higher than 99% and a misidentification rate smaller than 5%, for non-converted, isolated photons with energy higher than 1 GeV. To secure a decent $g(H\gamma\gamma)$ measurement and boson mass resolution with hadronic final states, the photon energy should be measured to a precision better than $20\%/\sqrt{E} \oplus 1\%$. To identify the τ leptons with different decay modes, the photons should be identified from the π^0 with an efficiency and purity higher than 95% at the $Z \rightarrow \tau^+\tau^-$ sample at CEPC Z pole operation.

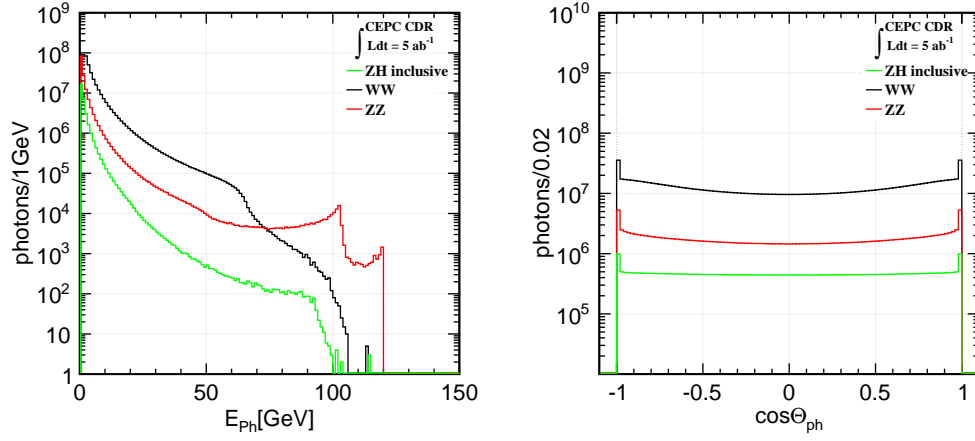

Figure 3.6: Energy and polar angle distribution of all photons at the leading physics processes at the CEPC Higgs operation.

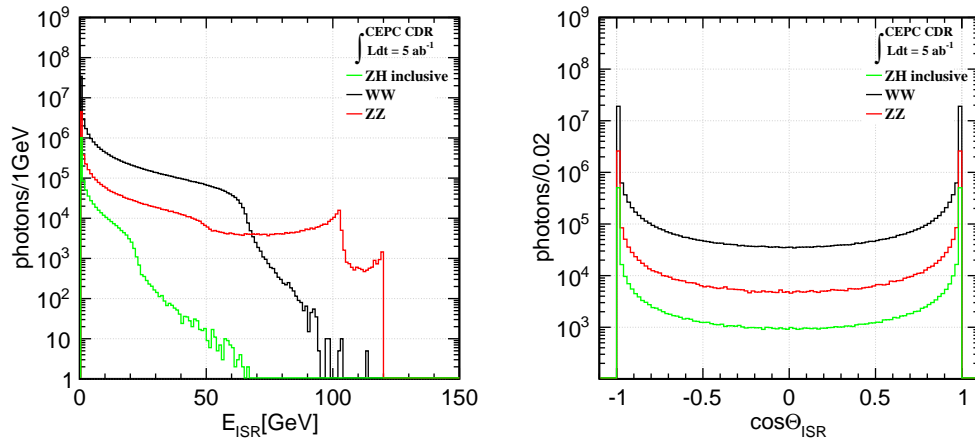

Figure 3.7: Energy and polar angle distribution of ISR photons from the leading physics processes at the CEPC Higgs operation.

3.2.6 Jets and Missing energy

The jet reconstruction is essential for the CEPC physics program, since the majority of W, Z, and Higgs bosons decays into hadronic final states. At the Particle Flow oriented design, the jet is constructed via clustering algorithms from the final state particles. Therefore, the jet reconstruction is determined by the reconstruction of final state particle, and the jet clustering algorithm. Consequently, the jet reconstruction performance should be evaluated at two stages.

The first is the Boson Mass Resolution (BMR) for massive SM bosons. The boson mass resolution represents the jet energy resolution with perfect jet clustering, or more accurately, a perfect identification of the color singlet. The BMR is defined as the relative resolution of the visible mass on the $vvH, H \rightarrow gluons$ events with a standard cleaning procedure. The cleaning procedure has a typical efficiency of 65%, it vetos the events with energetic visible ISR photon(s), energetic neutrinos generated in the Higgs decay, and jets pointing to the very forward regions. Since the width of the SM Higgs boson (4 MeV) is negligible comparing to the jet energy resolution (GeV), BMR is equivalently the Higgs mass resolution with cleaned $vvH, H \rightarrow gluons$ sample.

Fig. 3.8 shows the reconstructed H, W, Z boson mass with different BMR. In order to distinguish the W, Z, and the Higgs boson from their hadronic decay final state, a boson mass resolution better than 4% is required. It should be remarked that an efficient separation of individual W, Z, and Higgs boson is a pre-request for a clear separation of WW, ZZ, and ZH events with 4-jet final states, since the latter strongly depends on the jet clustering performance.

The missing energy measurement with jet final states can also be characterized by the BMR. The physics benchmark for the missing energy-momentum measurement is the $Br(H \rightarrow invisible)$ measurement with qqH final states. The signal has a Higgs mass peak in the missing mass spectrum. The dominant SM background, the $ZZ \rightarrow v\bar{v}q\bar{q}$ process, exhibit a peak at the Z boson mass. Meanwhile, because the initial state radiation and the heavy flavor component of the $Z \rightarrow q\bar{q}$ decay, both missing mass distributions exhibit a high mass tail. The missing mass distributions at different BMR are displayed in Fig. 3.9. At a BMR worse than 4%, the Z recoil mass peak of the background becomes so wide that it starts to overlap with the Higgs mass peak. Therefore, for this benchmark, a boson mass resolution better than 4% is certainly appreciated.

The identification of individual jet, and its energy-momentum reconstruction is crucial for the CEPC physics measurements. The individual jet energy response is highly depending on the event topology and the jet clustering algorithms. A detailed analyses is required to disentangle the actual physics requirement, which need to be analyzed profoundly.

3.2.7 Flavor Tagging

One of the key physics objectives of the CEPC Higgs program is to measure the $g(Hcc)$ coupling. The CEPC detector is therefore required to efficiently distinguish the b-jets, the c-jets, and the light jets from each other. A decent flavor tagging performance is also highly appreciated in EW precision measurements.

Benchmarked with the $Z \rightarrow q\bar{q}$ sample at 91.2 GeV c.m.s, we require the b-jets to be identified with a efficiency and purity higher than 80%, and a c-jet identification efficiency/purity better than 60%.

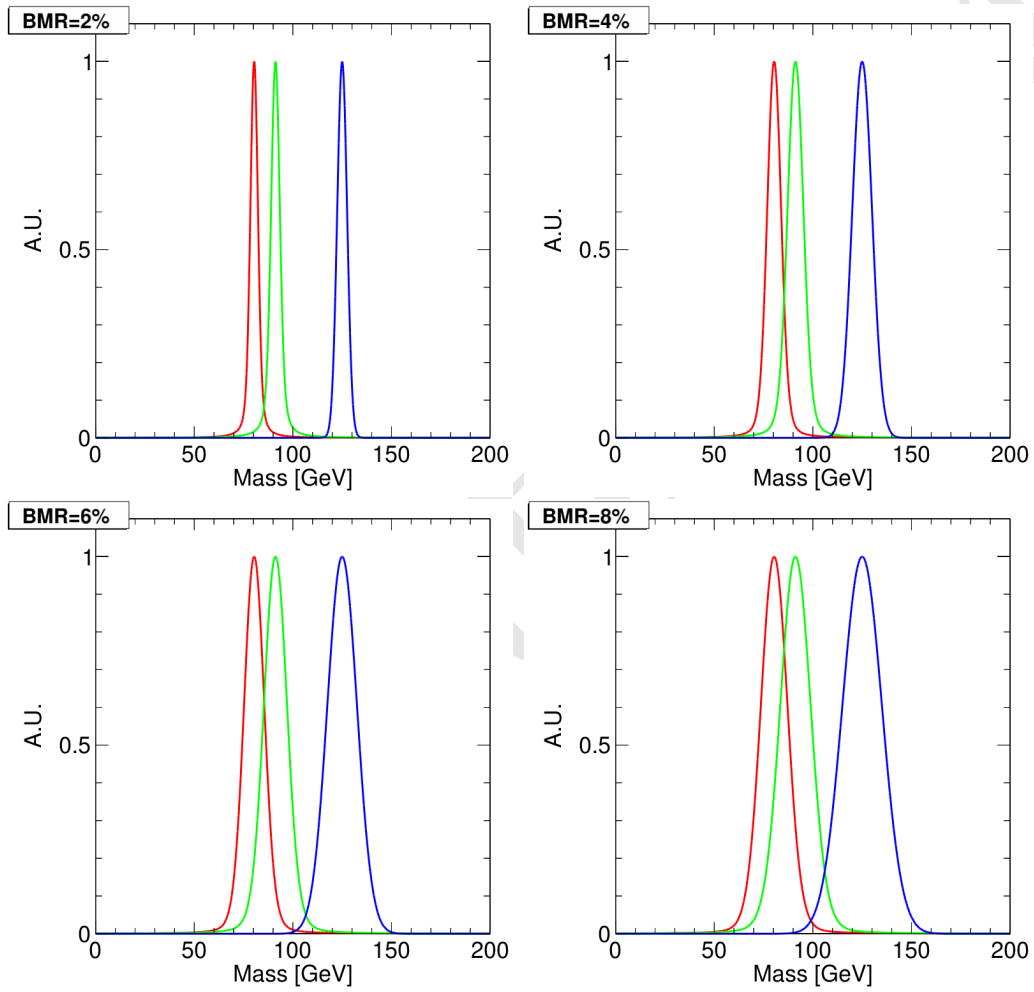

Figure 3.8: Invariant mass distribution of H, W, and Z bosons at different boson mass resolution. Normalized to unit height.

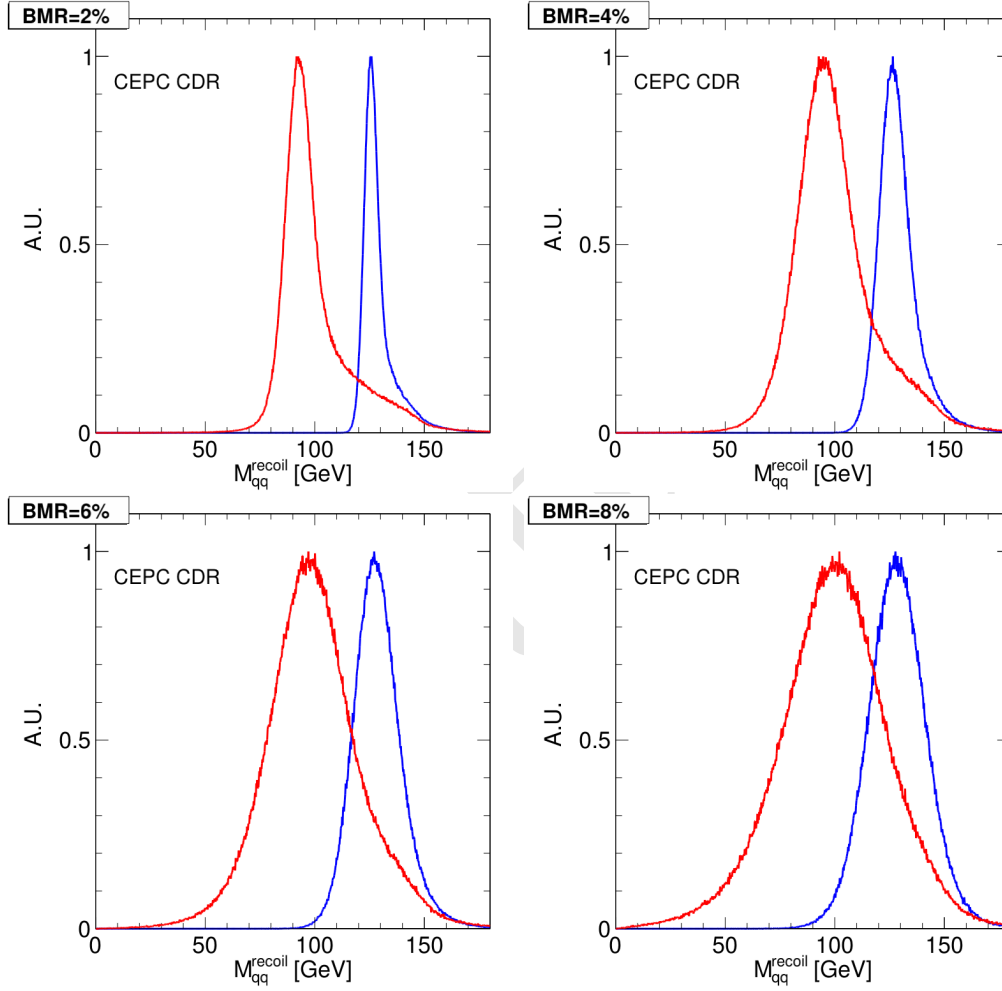

Figure 3.9: Recoil mass distribution of $ZZ \rightarrow \nu\nu q\bar{q}$ events and ZH events with Z decays into a pair of quark and Higgs decays invisibly.

The classification of different kinds of jets mainly relies on the reconstruction of secondary vertex, where the performance of the vertex system is crucial. The clean collision environment of the CEPC allows much aggressive vertex system design, a detailed vertex optimization study could be found in section ??.

3.2.8 Requirements on the physics objects: summary

The discussion above quantifies the physics requirements on the physics object reconstruction. It could be summarized as:

- 1, Tracking performance: For tracks with $E > 1 \text{ GeV}$ that within the detector acceptance, an reconstruction efficiency better than 99% is required. The relative resolution of the track momentum should achieve per mille level accuracy, required by the measurements of $g(H\mu^+\mu^-)$ and the Higgs recoil mass analyses with l^+l^-H events.
- 2, Excellent lepton identification. For isolated leptons with energy larger than 5 GeV, we request an identification efficiency of 99% and accumulated misidentification rate smaller than 2%. The leptons inside the jets also need to be identified decently, as they bring the information on the jet flavor and jet charge.
- 3, Capable to identify charged kaons, which enhances rich flavor physics program at CEPC Z pole operation. For the inclusive $Z \rightarrow q\bar{q}$ sample at 91.2 GeV c.m.s, we request a charged Kaon identification with efficiency and purity to be both higher than 90%.
- 4, Precise reconstruction of photons. Required by the $g(H\gamma\gamma)$ measurement and the jet energy reconstruction, the photon energy should be measured to a precision better than $20\%/\sqrt{E} \oplus 1\%$. Meanwhile, to identify the τ leptons with different decay modes, the photons should be identified from the π^0 with an efficiency and purity higher than 95% at the $Z \rightarrow \tau^+\tau^-$ sample at CEPC Z pole operation.
- 5, Good Jet/Missing Energy (MET) reconstruction. The jet/missing energy reconstruction is essential for the CEPC since most of the physics events are generated with either, or even both, of these physics objects. To avoid the complication from jet clustering performance, we characterize the jet and missing energy reconstruction with Boson Mass Resolution. Benchmarked with the separation of massive SM bosons (W, Z, and Higgs boson) and the $Br(H \rightarrow \text{invisible})$ measurements, a BMR better than 4% is identified.
- 6, Capable to separate b -jets, c -jets and light jets (uds and gluon jets): required by the $g(Hb\bar{b})$, the $g(Hc\bar{c})$, the $g(Hgg)$, and the EW measurements. Benchmarked with the $Z \rightarrow q\bar{q}$ sample at 91.2 GeV c.m.s, we require the b -jets to be identified with a efficiency and purity higher than 80%, and a c -jet identification efficiency/purity better than 60%.

Most of the above-mentioned requirements are driven by the precision Higgs measurements. However, it also applies to the precise EW measurements as the W and Z bosons decay into similar physics objects.

3.3 Detector concepts

To address the physics requirements at the CEPC, two(three) different detector concepts are proposed.

The first (two) detector concept(s) is (are) guided by the Particle Flow Principle. The Particle Flow principle interprets all the detector signal as the final state particles. For each physics event, all the physics objects are reconstructed from an unique list of final state particles. The single particle level physics objects, for example the leptons, the photons, and the kaons, are identified directly from the final state particle list. The composited physics objects, for example the converted photons, the K_s^0 , the τ lepton and the jets, are identified using dedicated finding algorithm such as tau finder and jet clustering algorithms. Subtracting the total visible four-momentum of all the final state particle from the initial four momentum determines the missing four-momentum. This global interpretation of the final state particles leads to high efficiency, and high purity reconstruction of all the physics objects. In addition, the Particle Flow algorithm in principle associate the detector hits to each individual particle, therefore, the final state particle could be measured in the most-suited sub-detector system. For the charged particles, the relative accuracy of track momentum resolution at the tracking system is usually much better than the energy resolution at calorimeter system. Therefore, the Particle Flow algorithm also significantly improves the accuracies on the energy reconstruction of composed objects, especially for the τ lepton and the jets.

The baseline detector geometry is named APODIS, stands for A Particle Flow Oriented Detector for the Higgs factory. It is developed from the concept of International Large Detector (ILD, the baseline detector for the linear colliders). It is optimized for the CEPC collision environments, and enhances the Particle identification performance which is essential for the flavor physics. Meanwhile, the total construction cost and the number of electronics are significantly reduced. The APODIS uses ultra high granularity calorimeter system to efficiently separate the final state particle showers, low material tracking system to limit the probability of interaction between final state particle to the tracking material, and large volume solenoid that host the entire ECAL and HCAL inside. There are two options for its tracking system, the TPC and the full silicon tracking.

An alternative detector geometry, IDEA, is also proposed. IDEA uses dual readout calorimeter to achieve a good energy resolution for both electromagnetic and hadronic showers. Comparing to APODIS, IDEA uses weaker solenoid but large tracker. The IDEA is also used as a reference detector for the FCC-ee studies.

The main geometry parameter of both concepts are summarized in Tabletab:detpara.

3.3.1 The baseline detector concept

From inner to outer, the baseline geometry is composed of a silicon pixel vertex system, a silicon internal tracker, a TPC main tracker, a Silicon-tungsten sampling ECAL, see Fig. 3.10 a Iron-Glass Resistive Plate Chamber HCAL, a solenoid, and a return Yoke.

The baseline geometry has a dedicated design on the forward region and the MDI. The L^* of the baseline geometry has a length of 2.2 meters, and a compensation solenoid system is installed at z position of 1100 - 6000 mm. A LumiCal is installed at the end of this nose. A compact, forward tracking system composed of 5 pairs of tracking disks is installed in between z position of 200 - 1000 mm.

Concept	ILD	APODIS	IDEA
Tracker	TPC/Silicon	TPC/Silicon	Drift Chamber/Silicon
Solenoid B-Field (T)	3.5	3	2
Solenoid Free Bore (m)	3.3		2.1
Solenoid Length (m)	8.0		6.0
L* (m)	3.5	2.2	2.2
VTX Inner Radius (mm)	16	16	16
Tracker Outer Radius (m)	1.8	1.8?	2.05
Pairs of forward tracking disks	7	5	5
Calorimeter	PFA	PFA	Dual readout
Calorimeter λ_I	5.5		7.5
ECAL Cell Size (mm)	5	10	-
ECAL Time resolution (ns)	-?	200 ps/hit	-
HCAL Layer Number	48	40	-
HCAL Absorber	Fe		-
DRCAL Cell Size (mm)	-	-	6.0
DRCAL Time resolution (ns)	-	-	100 ps/hit
DRCAL Absorber	-	-	Pb or Cu or Fe
Overall Height (m)	14.0		11.0
Overall Length (m)	13.2		13.0

Table 3.2: Comparison of detector parameters. Do we need the number of forward tracking disks? We would need to mention the barrel silicon as well. The tracker outer radius needs to include the last silicon layer. Check absorbers.

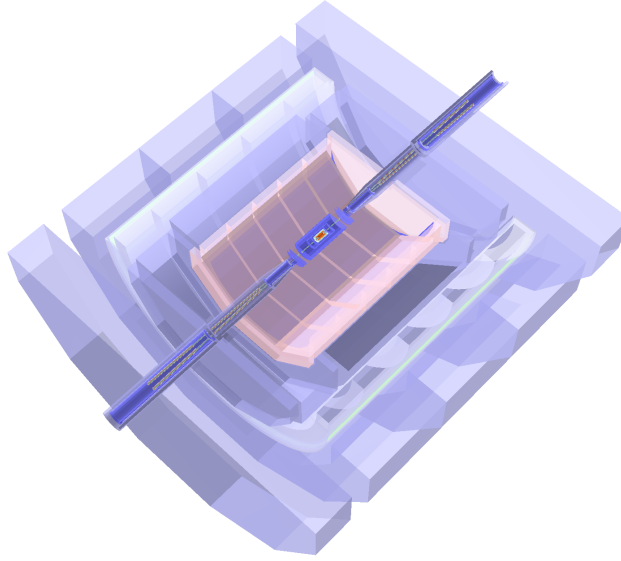

Figure 3.10: Sliced view of the baseline detector geometry for the CEPC CDR study. The baseline geometry uses double beam with 33 mrad cross angle, and have a short L^* of 2.2 meter. In its Barrel, from inner to outer, the baseline geometry is composed of a Vertex system (Red), a Silicon Inner Tracker (Deep Blue), a TPC, a Silicon External Tracker, a ECAL (Pink), a HCAL (Violet), a Solenoid of 3 Tesla and a Return Yoke. In its forward region, 5 pairs of tracking disks is installed to enlarge the detector acceptance.

The solenoid B-Field of the baseline is 3 Tesla. The CEPC uses double ring configuration, with a cross angle of 33 mrad at the interaction point. Each time the bunch passing through the detector, the beam emittance increases via the coupling to the detector solenoid B-Field (especially the vertical emittance). In order to achieve a high luminosity, this solenoid B-Field needs to be compensated locally. Therefore, a compensating solenoid is installed in the forward region of the CEPC detector. Considering the technology challenge of the compensating solenoid and the physics requirement at the CEPC, The baseline geometry uses a solenoid of 3 Tesla for the CEPC Higgs operation, and the central solenoid might be further reduced to 2 Tesla for the CEPC Z pole operation.

The baseline geometry uses the Time Projection Chamber (TPC) as its main tracker. The TPC provides good energy resolution, excellent track reconstruction efficiency, low material budgets, and its dE/dx measurement is essential for the particle identification, see section ???. On the other hand, compared to the silicon tracking, the TPC is a slow technology: the drift time of ions is of the order of one second at the APODIS TPC. At TPC, both primary ionization of charged tracks and ion backflow from the amplification procedure generates ions, which accumulate in the gas volume. These ions will distort the drift electric field and eventually limit the precision of track momentum measurement. The physics event rate at the CEPC Z pole operation is of the order of 10^{3-4} Hz, therefore, ions generated from thousands of events pile up in the gas volume. The control of backflow ion is then essential for the TPC operation.

Iterated with the hardware R&D, dedicated simulation studies are performed at the CEPC TPC study. Using double amplification layer, the ion backflow could be controlled to per mille level without gating [?]. On the other hand, the simulation analysis shows that at this level of ion backflow control, the degrading of spatial point resolution is smaller

than the intrinsic TPC spatial resolution. The TPC occupancy is also analyzed at the TPC Z pole. Those studies lead to the conclusion that the TPC is a feasible technology option for the CEPC [6].

The TPC in the baseline has an inner radius of 0.3 meters, an outer radius of 1.8 meters, and a length of 4.7 meters. It is divided into 220 radial layers, each has a thickness of 6 mm. Along the ϕ direction, each layer is segmented into 1 mm wide cells. In total, the TPC has 10 million readout channels in each endcap. Operating in 3 Tesla solenoid B-Field, the TPC provides a spatial resolution of $100 \mu\text{m}$ in the $R - \phi$ plane and $500 \mu\text{m}$ resolution in the Z direction for each tracker hit. The TPC reaches a standalone momentum resolution of $\delta(1/P_t) \sim 10^{-4} \text{GeV}^{-1}$.

The baseline is equipped with large-area silicon tracking devices, including the pixel vertex system, the forward tracking system, and the silicon inner/external tracking layers located at the boundary of the TPC. Combining the measurements from the silicon tracking system and the TPC, the track momentum resolution could be improved to $\delta(1/P_t) \sim 2 \times 10^{-5} \text{GeV}^{-1}$. In fact, the TPC is mainly responsible for the pattern recognition and track finding, while the silicon tracking devices dominate the momentum measurement. The silicon pixel vertex system also provides precise impact parameter resolution ($\sim 5 \mu\text{m}$), which is highly appreciated for the τ lepton reconstruction and the jet flavor tagging.

The baseline geometry uses high granular sampling Electromagnetic Calorimeter (ECAL) and Hadronic Calorimeter (HCAL). The calorimeter is responsible for separating final state particle showers, measuring the neutral particle energy, and providing information for the lepton identification [7][8]. The entire ECAL and HCAL are installed inside the solenoid, providing 3-dimensional spatial position and the energy information. The ECAL geometry parameter is determined by a dedicated optimization study [9]. The ECAL is composed of 30 layers of alternating silicon sensor and tungsten absorber. It has a total absorber thickness of 84 mm. Transversely, each sensor layer is segmented into 10 mm by 10 mm cells. The HCAL uses Resistive Plate Chamber sensor and Iron absorber. It has 40 longitudinal layers, each consists of a 25 mm Iron absorber. Transversely, it is segmented into 10 mm by 10 mm cells.

This calorimeter system provides decent energy measurement for the neutral particles (i.e. roughly $16\%/\sqrt{E/\text{GeV}}$ for the photons and $60\%/\sqrt{E/\text{GeV}}$ for the neutral hadrons). More importantly, it records enormous information of the shower spatial development, ensuring efficient separation between nearby showers and providing essential information for the lepton identification, see section ???. In addition, the silicon tungsten ECAL could provide precise time measurement. Requesting a cluster level time resolution of 50 ps, the ECAL Time of Flight (ToF) measurement plays a complementary role to the TPC dE/dx measurement, leading to a decent charged Kaon identification performance, see section ??.

As will be introduced in the following chapter, the baseline geometry maintains the same performance for the CEPC Higgs measurements comparing to the ILD. Meanwhile, the total cost, the total weight, and the calorimeter thickness have been significantly optimized (by 25%, 50% and 20% respectively). In addition, the baseline geometry has a good performance in charged kaon identification, which is highly appreciated in the flavor physics and in the jet flavor/charge reconstruction.

3.3.2 Full silicon detector concept

3.3.3 An alternative low magnetic field detector concept

The baseline detector described in this CDR is a very straightforward evolution of the ILD detector originally conceived for the International Linear Collider (ILC) [10]. We propose here a new detector concept, IDEA (Innovative Detector for Electron-positron Accelerator), that is specifically designed for a circular electron-positron collider and also attempts to contain the overall cost of the detector.

While most detector requirements needed for detectors at ILC are very similar to those for CepC [11], there are however some notable differences. First of all the typical luminosity expected both at the Z pole ($\sqrt{s} = 90 \text{ GeV}$) and above the ZH threshold ($\sqrt{s} = 240 \text{ GeV}$) is expected to be one or two orders of magnitude larger, with a much shorter bunch spacing and no large time gaps in the beam structure. This places severe constraints on the tracking system. In particular one would prefer an intrinsically fast main tracker to fully exploit the cleanliness of the e^+e^- environment while integrating as little background as possible, and a very low power vertex detector, since power pulsing is not allowed by the bunch spacing. Additional issues of emittance preservation, typical of circular machines, set limits on the maximum magnetic field usable for the tracker solenoid, especially when running at the lower energy. This could be a problem for a large volume TPC, due to the resolution degradation, and also for a silicon tracker, since it would require more layers at a large radius, thus significantly increasing the cost.

Additional specific requirements on a detector for CepC come from precision physics at the Z pole, where the statistical accuracy on various electro-weak parameters is expected to be over an order of magnitude better than at the ILC. This calls for a very tight control of the systematic error on the acceptance, with a definition of the acceptance boundaries at the level of a few μm , and a very good $e - \gamma - \pi_0$ discrimination to identify τ leptons efficiently and measure their polarization. A layer of silicon microstrip detectors around the main tracker can provide the needed acceptance control for charged tracks, while also improving the tracking resolution. Similarly, the acceptance accuracy and improved identification efficiency of γ 's can be obtained with a pre-shower based on MPGD detectors located just outside the detector magnet, which serves as a radiator.

The particle flow calorimeters, currently proposed for both ILC and CLIC, feature an extremely large number of readout channels and require significant data processing to obtain the optimal performance. A cheaper and more effective calorimeter can be made using the dual readout technique [12], which has been extensively studied and demonstrated in over ten years of R&D by the DREAM/RD52 collaboration [13, 14]. With this technology the electromagnetic and hadronic calorimeters come in a single package that plays both functions and allows an excellent discrimination between hadronic and electromagnetic showers [15]. Since all the readout electronics is located in the back of the calorimeter, its cooling is greatly simplified relative to the case of particle flow calorimeters.

Finally recent developments in multi-pattern gas detector technology, such as μRwell [16], can significantly reduce the cost of large area tracking chambers to be used for tracking muons outside the calorimeter volume.

The IDEA detector The structure of the IDEA detector is outlined in figure 3.11, which also shows its overall dimensions.

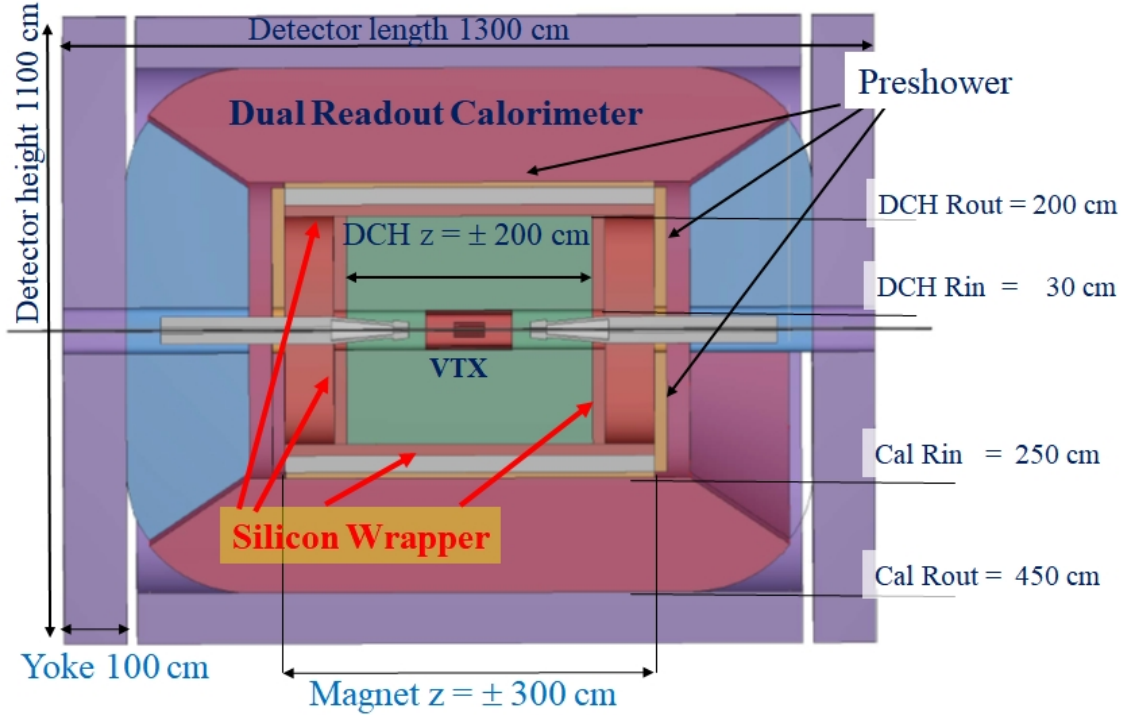

Figure 3.11: Schematic layout of the IDEA detector.

A key element of IDEA is a thin, ~ 30 cm, and low mass, $\sim 0.8 X_0$, solenoid with a magnetic field of 2 Tesla. This field is optimal, according to studies done for FCC-ee, as it minimizes the impact on emittance growth and allows for manageable fields in the compensating solenoids [17], but it is certainly not optimal for a large TPC or a silicon tracker of reasonable size. The low mass and thickness allows to locate the calorimeter outside the tracking volume without a significant performance loss.

The innermost detector, surrounding the 1.5 cm radius beam pipe, is a silicon pixel detector for the precise determination of the impact parameter of charged particle tracks. Recent test beam results on the detectors planned for the ALICE inner tracker upgrade (ITS), based on the ALPIDE readout chip [18], indicate an excellent resolution, $\sim 5 \mu\text{m}$, and high efficiency at low power and dark noise rate [19]. This looks like a good starting point for the IDEA vertex detector and a similar approach is proposed for the CepC baseline detector (see section 4.5). The two detector concepts could then share the same pixel technology as well as profit from the electronic and mechanical work of the ALICE ITS.

Outside the vertex detector we find a 4 m long cylindrical drift chamber starting from a radius of ~ 35 cm and extending until 2 m. The chamber can be made extremely light, with low mass wires and operation on 90% helium gas; less than 1% X_0 is considered feasible for 90° tracks. Additional features of this chamber, which is described in detail in section 6.3, are a good spatial resolution, $< 100 \mu\text{m}$, dE/dx resolution at the 2% level and a maximum drift time of only 400 nsec. A layer of silicon microstrip detectors surrounds the drift chamber in both barrel and forward/backward regions. Track momentum resolution of less than 0.5% for 100 GeV tracks is expected when vertex detector and silicon wrapper information is included in the track fit. It is worth noting that the design of this chamber is the evolution of work done over many years on two existing chambers, that of the KLOE

detector [20] and that of the recent MEG experiment upgrade [21]; major R&D work was done also for the 4th concept at ILC [22] and then for the Mu2E tracker [23].

A pre-shower is located between the solenoid magnet and the calorimeter in the barrel region and between the drift chamber and the end-cap calorimeter in the forward region. This detector consists of two passive material radiators each followed by a layer of MPGD detectors. In the barrel region the solenoidal magnet plays the role of the first radiator, while in all other cases the radiators are made of lead. The actual thickness of the radiators are still being optimized based on test beams currently in progress. In the extreme case of using a total of two radiation lengths about 75% of the π^0 's can be tagged by having both γ 's from their decay identified by the pre-shower. Additional π^0 identification power comes from the high granularity of the calorimeter.

A solenoidal magnet surrounds the tracking system and the first pre-shower layer. Presently planned dimensions are 6 m of length and 4.2 m inner diameter. The relatively low two Tesla field and the small dimensions have important implications on the overall magnet package thickness, that can be kept at the 30-40 cm level, and on the size of the flux return yoke, which scales linearly with the field and the square of the coil diameter. With the given dimensions a yoke thickness of less than 100 cm of iron is sufficient to completely contain the magnetic flux and provide adequate shielding and support for the muon chambers.

A dual readout fiber calorimeter (see section 7) is located behind the second pre-shower layer. We assume a total calorimeter depth of 2 m, corresponding to approximately seven pion interaction lengths. The detector resolution is expected to be about $10.5\%/\sqrt{E}$ for electrons and $35\%/\sqrt{E}$ for isolated pions with negligible constant terms, as obtained from extrapolations from test beam data using GEANT4 without including the pre-shower. This detector has very good intrinsic discrimination between muons, electrons/photons and hadrons for isolated particles [15]. This discrimination power is further enhanced when the information of the pre-shower and the muon chambers is added, extending the separation power also into hadronic jets and making it suitable for the application of particle-flow-like algorithms. The intrinsic high transverse granularity provides a good matching of showers to tracks and pre-shower signals.

The muon system consists of layers of muon chambers embedded in the magnet yoke. The area to be covered is substantial, several hundreds of square meters, requiring an inexpensive chamber technology. Recent developments in the industrialization of μ Rwell based large area chambers, as planned for the CMS Phase II upgrade, are very promising (see section 9).

Conclusions A different concept for a detector at CepC has been proposed. This detector is designed specifically for CepC and its specific running conditions and physics goals. In particular it is safe with respect to interaction between the detector solenoid field and the beam. Although additional R&D to optimize performance, reduce costs and come to a detailed engineered design of the detector is still necessary, this detector is based on technologies which are established after many years of R&D and whose feasibility has by large been established. Furthermore several choices are made to simplify the detector structure and reduce the cost, which in the end should be smaller than for an ILD-like detector.

Draft-V0.4

CHAPTER 4

TRACKING SYSTEM

4.1 Vertex tracker detector

The identification of heavy-flavor (b- and c-) quarks and τ leptons is essential for the CEPC physics program. It requires precise determination of the track parameters of charged particles in the vicinity of the interaction point (IP), permitting reconstruction of the displaced decay vertices of short-lived particles. This drives the need for a vertex detector with low material budget and high spatial resolution. The baseline design of CEPC vertex detector is a cylindrical barrel with six silicon pixel layers and optimized for the energy regime and utilizes modern sensors.

4.1.1 Performance Requirements and Detector Challenges

As required for the precision physics program, the CEPC vertex detector is designed to achieve excellent impact parameter resolution, which in the $r\phi$ plane can be parameterized by:

$$\sigma_{r\phi} = a \oplus \frac{b}{p(\text{GeV}) \sin^{3/2}\theta} \quad (4.1)$$

where $\sigma_{r\phi}$ denotes the impact parameter resolution, p the track momentum, and θ the polar track angle. The first term describes the intrinsic resolution of the vertex detector in the absence of multiple scattering and is independent of the track parameters, while the second term reflects the effects of multiple scattering. $a=5 \mu\text{m}$ and $b=10 \mu\text{m} \cdot \text{GeV}$ are taken as the design values for the CEPC vertex detector. The main physics performance goals can be achieved with a three-layer pixellated vertex detector with the following characteristics:

- Single-point resolution near the IP better than $3 \mu\text{m}$;

- Material budget below $0.15\% X_0/\text{layer}$;
- First layer located close to the beam pipe at a radius of 16 mm, with a material budget of $0.15\% X_0$ for the beam pipe;
- Detector occupancy not exceeding 1%.

The power consumption of the sensors and readout electronics should be kept below $50 \text{ mW}/\text{cm}^2$, if the detector is air cooled. The readout time of the pixel sensor needs to be shorter than $20 \mu\text{s}$, to minimize event accumulation from consecutive bunch crossings. The radiation tolerance requirements, which are critical for the innermost detector layer, are driven by the beam related backgrounds as described in Chapter 9.

4.1.2 Baseline design

The baseline layout of the CEPC vertex detector consists of three concentric cylindrical layers of double-sided pixellated silicon detector located between 16 and 60 mm from the beam line. The ladders, which are the main mechanical structure, support high spatial resolution silicon pixel sensors on both sides. The CEPC vertex detector is designed to deliver six precise space-points for charged particle traversing the detector. The material budget of each detector layer amounts to $\sim 0.15\% X_0$. Extensive simulation studies (see Section 4.1.3) show that the chosen configuration with the single-point resolutions listed in table 4.1 achieves the required impact parameter resolution.

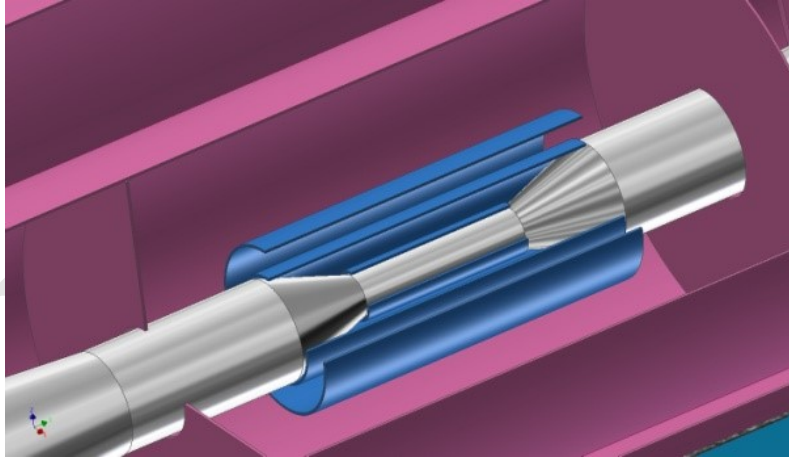

Figure 4.1: Schematic view of pixel detector (blue)

4.1.3 Detector performance studies

The identification of b/c-quark jets (called "flavor-tagging") is essential in physics analysis where signal events with b/c-quark jets in the final state have to be separated. Flavor tagging requires the precise determination of the impact parameter of charged tracks embedded in the jets. For CEPC operation at the center-of mass energy of 240 GeV, those tracks are often of low momentum, for which the multiple scattering effect dominates the tracking performance as illustrated by Eq. 4.1.

The CEPC vertex detector layout has been fully implemented in the GEANT4-based simulations framework MOKKA [1]. In addition, the LiC Detector TOY fast simulation

	$R(mm)$	$ z (mm)$	$ \cos\theta $	$\sigma(\mu m)$	Readout time(us)
Layer 1	16	62.5	0.97	2.8	20
Layer 2	18	62.5	0.96	6	1-10
Layer 3	37	125.0	0.96	4	20
Layer 4	39	125.0	0.95	4	20
Layer 5	58	125.0	0.91	4	20
Layer 6	60	125.0	0.90	4	20

Table 4.1: Vertex detector parameters

and reconstruction framework (LDT) [2] have been used for detector performance evaluation and layout optimization. The preliminary studies for optimization to evaluate the sensitivity of the results on the chosen parameters have been done, for the purpose of assessing the impact of the detector geometries and material budgets on required flavor-tagging performance. However, beam-induced background was not included at the moment.

4.1.3.1 Performance of the Baseline Configurations

The impact parameter resolution following from the single-point resolutions provided in the table 4.1 is displayed in figure 4.2 as a function of the particle momentum, showing that the ambitious impact parameter resolution is achievable.

**Figure 4.2:** Transverse impact-parameter resolutions for single muon events as a function of the momentum for different polar angles.

4.1.3.2 Material Budget

The baseline design includes very small material budget for the beam pipe as well as for the sensor layers and their support. To assess the sensitivity of the performance on the amount of material, the material budget of the beam pipe and the vertex detector layers has been varied. The resulting transverse impact-parameter resolutions for low-momentum tracks are shown in Figure 4.3. When increasing the material of the detector layers by a factor of two, the resolution degrades by approximately 20%.

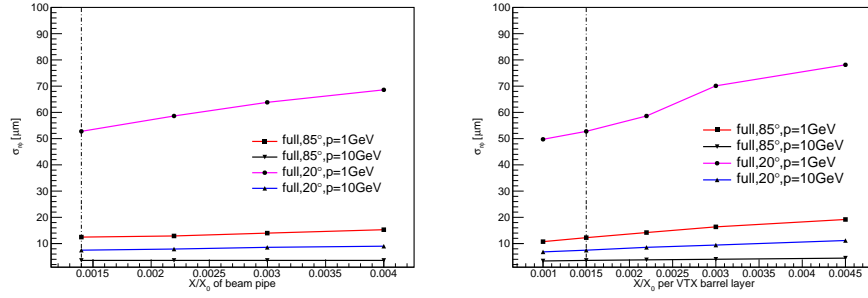

Figure 4.3: Transverse impact-parameter resolution as function of the amount of material inside the beam pipe (left) and inside the vertex barrel double layers (right), as obtained from the simulation. The results are shown for 1 GeV and 10 GeV tracks and for polar angles of $\theta=20$ degrees and of $\theta=85$ degrees. The material budget corresponding to the baseline configuration is indicated by dashed lines.

4.1.3.3 Dependence on Single-Point Resolution

The dependence of the transverse impact-parameter resolution on the pixel size was studied by worsening the single-point resolution of the vertex layers by 50% w.r.t. the baseline values. The resulting impact parameter resolution for high and low momentum track as function of the polar angle θ is shown in Figure 4.4. The resolution for track momenta of 100 GeV is found to change by approximately 50% in the barrel region, which is totally expected. Here they are better than the target value for the high-momentum limit of $a \approx 5 \mu\text{m}$ in both cases, as expected from the corresponding single-point resolutions. For 1 GeV, where multiple-scattering effects dominate and the corresponding variation of the transverse impact-parameter resolution is only 10% larger. The target value for the multiple-scattering term of $b \approx 10 \mu\text{m} \cdot \text{GeV}$ is approximately reached in both cases. It should be noted, however, that the pixel size is also constrained by the background occupancies (see Section 4.1.4) and the ability to separate adjacent tracks in very dense jets in the presence of such backgrounds.

4.1.3.4 Distance to IP

The distance of the first double vertex layer from the IP was varied by ± 4 mm relative to baseline geometry of the CEPC vertex detector. Figure 4.5 shows the resulting transverse impact parameter resolution at $\theta=85$ degrees as function of the momentum and for different radial distance of the innermost barrel vertex layer from the IP. For low momentum tracks, the transverse impact-parameter resolution is proportional to the inner radius, as expected from the parameter formula.

4.1.4 Beam-induced Background in the Vertex Detector

The pair-production and off-energy particles are expected to be the dominating source of detector backgrounds originating from the interaction region. These processes have been studied with detailed Monte Carlo simulation in Chapter 9. For the first vertex detector layer, the maximum annual values of the Total Ionising Dose (TID) and Non-Ionising Energy Loss (NIEL) are estimated to be 3.4 MRad and $6.2 \times 10^{12} \text{ 1 MeV n}_{\text{eq}}/\text{cm}^2$ respectively, with a safety factor of 10 included (see Table 9.4 in Chapter 9). This happens

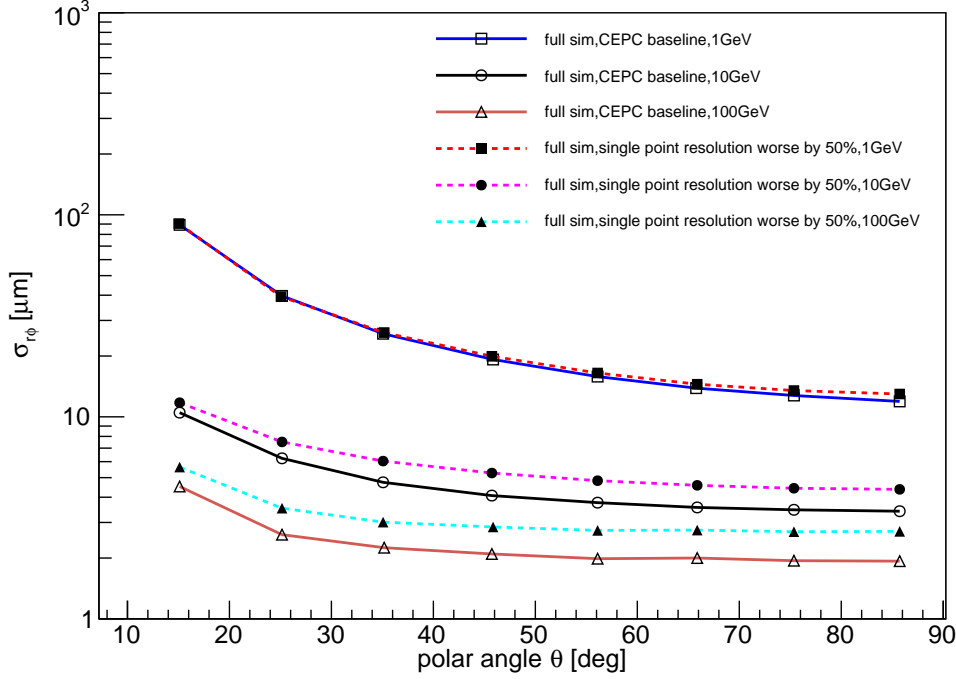

Figure 4.4: Transverse impact-parameter resolutions as function of the polar angle theta for different values of the single-point resolution of the CEPC barrel vertex detector. Shown are the resolutions for 1 GeV, 10 GeV and 100 GeV tracks.

when the machine operating in Z-pole energy, and imposes radiation tolerance as the requirement of silicon pixel sensor and associated readout electronics.

	H(240)	W(160)	Z(91)
Hit density (hits · cm ⁻² · BX ⁻¹)	2.4	2.3	0.25
Bunching spacing (μs)	0.68	0.21	0.025
Occupancy (%)	0.16	0.50	0.46

Table 4.2: Occupancies of the first vertex detector layer at different machine operation energies

The beam-induced background will have impacts on vertex detector occupancy, which is critical for the innermost detector layer. Table 4.2 shows the expected hit density and occupancies of the first vertex detector layer at different machine operation energies. The result of occupancies depends on assumptions of detector readout time and average cluster size. Here we assume a 20 μs of readout time for silicon pixel sensor and an average cluster size of 9 pixels per hit, where a pixel is taken to be 16×16 μm². The resulting maximal occupancy at each machine operation mode is below 1%.

4.1.5 Sensor Technology Options

Significant progress has been made over the 20 years since the first silicon pixel detector was introduced in the DELPHI detector [3] at LEP in 1995. Considerable R&D efforts

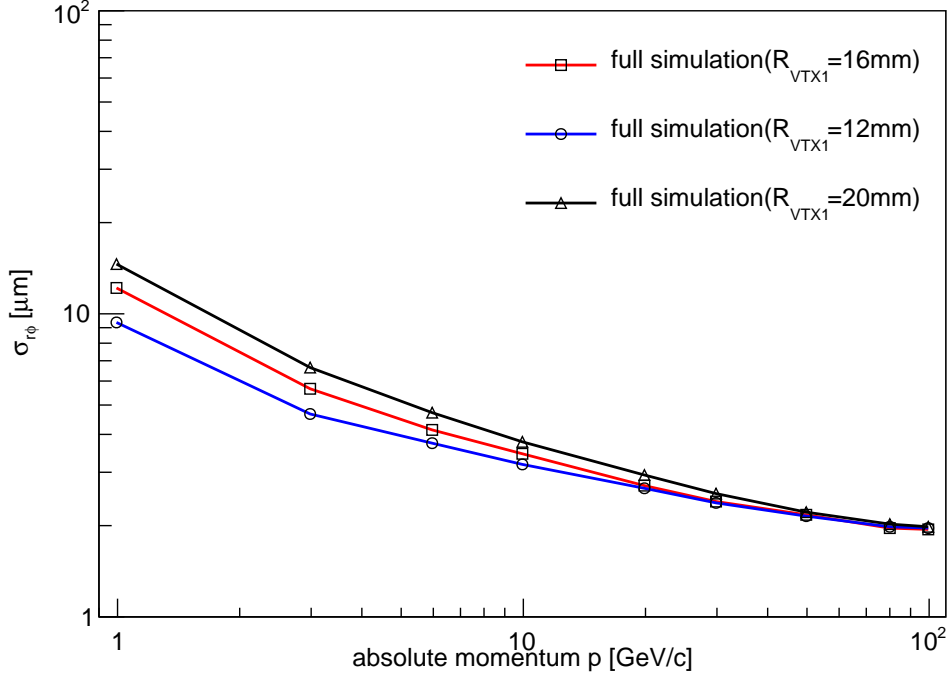

Figure 4.5: Transverse impact-parameter resolution at $\theta=85$ degrees as function of the momentum for different values of inner most layer radius R_{min} . The red curve indicates the baseline configuration of $R_{min}=16$ mm.

have taken place to develop pixel sensors for vertex tracking at future particle physics experiments [4], driven by track density, single-point resolution and radiation level.

As outlined in Section 4.1.1, the detector challenges for the CEPC include high impact-parameter resolution, low material budget, low occupancy and sufficient radiation tolerance (mild comparing to LHC but not necessarily easy to achieve). To fulfill these requirements at system level, sensor technologies which achieve fine pitch, low power and fast readout must be selected. In fact the CEPC vertex detector is more demanding than previous applications. CEPC is continuous, and power pulsing cannot be utilized to reduce average power. Other experiments such as the STAR[5], BELLEII[6] and ALICE upgrade[7] readout continuously as the CEPC. However, they have less stringent requirements in terms of impact-parameter resolution and material budget.

The monolithic pixel sensor has the potential to satisfy the low-material and high-resolution requirements of the CEPC vertex detector. This technology has been developing fast. The 1st generation MAPS-based vertex detector for STAR HFT upgrade [5, 8] just completed 3-year physics run successfully, while the new generation HR CMOS Pixel Sensor for ALICE-ITS upgrade [7] is in mass production. In the previous $0.35 \mu\text{m}$ double-well process, only N-MOS transistors can be used in the pixel design. This constraint is removed in the new $0.18 \mu\text{m}$ quadruple-well process. Both N and P-MOS transistors can be used in the pixel design. Combining with the smaller feature size, it becomes a very appealing technology. A good start point for the CEPC vertex would be the ALPIDE design [9], which is developed for the aforementioned ALICE-ITS upgrade and has achieved performances very close to the requirements of the CEPC. Further R&Ds are needed to

shrink the pixel pitch to $16\ \mu\text{m}$ (binary readout) in order to accomplish the required $2.8\ \mu\text{m}$ single-point resolution. Another monolithic option is the Silicon On Insulator (SOI) pixel sensor. After more than 10 years evolution, SOI has entered a new stage of maturity. Fundamental issues, including the transistor shielding [10] and the TID tolerance [11], have been addressed and wafer thinning [12] has been demonstrated. In the meanwhile, R&Ds for the ILC and the CLIC [13, 14] are exploring time stamping and analog readout scheme. The SOI has a unique feature of fully-depleted substrate as the active silicon. And its $0.2\ \mu\text{m}$ CMOS process provides the necessary density of transistors as the $0.18\ \mu\text{m}$ CMOS in HR CMOS does. Therefore it is envisaged that the readout design for the CEPC vertex may be adapted for both processes and to exploit each one's potentials.

Depleted P-channel Field Effect Transistor (DEPFET) is referred to as semi-monolithic because it allows to integrate the first amplification stage into the pixel combined with subsequent processing circuit in separate readout ASICs. The BELLE II is anticipating its full detector operation with the DEPFET-based vertex [6] installed at the end of 2018. It is very helpful to have the readout ASICs located outside the detector acceptance area as the major heat sources, while keeping the sensors exceptionally low power and low material. The challenge is to periodically sample the modulated current over a large pixel array within required intervals, $20\ \mu\text{s}/\text{frame}$ or even less.

Hybrid pixel has been used at hadron colliders for the past decades, and now CLIC R&D is pushing for $50\ \mu\text{m}$ thinned sensors bump bonded on $25\ \mu\text{m}$ pitch to $50\ \mu\text{m}$ thinned ASICs [15]. The hybrid approach evolves constantly and profits from industrial technology developments. Apart from the Very Deep Sub-Micron (VDSM) ASIC technology that enables complex functionalities and superior performances, a close watch on industrial developments of the vertical and lateral inter-connection technologies will also be very helpful to meet the material budget.

4.1.6 Mechanics and Integration

The design of the vertex detector is conceived as a barrel structure with three concentric cylinders of double-sided layers. Each double-sided layer is equipped with pixel sensors on both sides, and has a common support frame. In the azimuthal direction, each layer is segmented in elements called ladders. The ladder, which extends over the whole length of the layer, is the basic building block of the detector. It contains all structural and functional components, such as chips, flex cable, support frame and cold plate if it is necessary. Pixel chips in a row are connected to flex cable by wire bonding or other bonding techniques, and then glued to the support frame, which is composed of low Z materials, such as carbon fiber and silicon carbide, providing stable mechanical support. The other side of the support frame is equipped with another layer of pixel sensors.

The design of the ladders should take into account the specifications of the vertex detector. In order to reduce a small multiple Coulomb scattering contribution to the charged-track vertex resolution and control deformations from gravity and cooling forces for the sensors position stability, the ladder mechanical support must fulfill stringent requirements in terms of minimum material budget and highest stiffness. Ladder designs similar to the STAR pixel detector, the ALICE ITS, the BELLE II PXD, and the ILD double-sided ladder are under consideration.

The ladder mechanical support is inherently linked to the layout of the cooling system that will be adopted to remove the heat dissipated by the pixel sensors since the cooling

system is integrated in the mechanical structure. The cooling system of the CEPC vertex detector must balance the conflicting demands of efficient heat dissipation with a minimal material budget. Therefore a suitable, high thermal conductivity and low material budget, cold plate coupled with pixel sensors should be implemented in the ladder design. There are two main types of cooling methods in particle physics experiments, air cooling and active cooling. Table 4.3 gives a list of cooling methods and the corresponding material of each layer of the aforementioned experiments. The upgrade of ALICE ITS [7] adopts water cooling with respect to a chips power dissipation value of 300 mW/cm^2 . Polyimide cooling pipes fully filled with water are embedded in the cold plate. STAR- PXL [16] uses air cooling according to its chips power consumption of 170 mW/cm^2 . For ILD [17] vertex system, two different cooling options are considered, depending on the sensor technology. The sensors and SWITCHER chips of BELLE II PXD [18] require air cooling, while active cooling will be used for readout chips on each end of the detector, which is out of the sensitive region of the detector. So for CEPC vertex detector, the suitable cooling method will be determined according to the sensor option and the power consumption.

Vertex detector	Power dissipation	Cooling method	Material budget requirement/layer
Alice ITS	300 mW/cm^2	water	0.3%
STAR PXL	170 mW/cm^2	air	0.39%
ILD vertex	$<120 \text{ mW/cm}^2$ (CPS and DEPFET)	air or N_2	0.15%
	35W inside cryostat (FPCCD)	two-phase CO_2	
BELLEII PXD	20W for sensor and SWITCHER	Air	0.2%
	180W on each end	CO_2	

Table 4.3: Cooling method of the vertex detector in each experiment

Simulation and module prototype studies should be carried out to find suitable designs that can meet requirements of stability, cooling and the performance of the vertex detector.

For the design of the whole mechanical structure of the vertex detector, some criteria must be taken into account. Firstly, minimum material has to be used in the sensitive region to reduce multiple Coulomb scattering. Secondly, to ensure high accuracy in the relative position of the detector sensors and provide an accurate position of the detector with respect to the central tracker of TPC and the beam pipe, a mechanical connector or locating pin at each end of the ladder should be considered to allow the fixation and alignment of the ladder itself on the end rings. Thirdly, cooling system should be arranged reasonably to ensure stable heat dissipation. At last, to reduce the dead region caused by the boundary of each ladder, neighboring ladders should be partially superimposed.

In addition, the main mechanical support structures of the vertex should also meet the requirements of the integration with the other detectors, such as time projection chamber (TPC) and forward tracking disks.

4.1.7 Critical R&D

The inner most layers have to fulfill the most demanding requirements imposed by the physics program. In addition, the system is bounded by stringent running constraints. The technology options in Section 4.1.5 are able to meet each individual requirement, including single-point resolution, low material budget, fast readout, low power consumption and radiation tolerance, but R&D is needed to select the specific design which can achieve the combination of all these criteria. Due to the limited manpower and availability of process, presently R&D efforts have been put into CMOS and SOI pixel sensor development to address the challenges concerning single-point resolution and low power consumption. Further developments are foreseen to follow in the future, including enhancement of density, radiation hardness and ultra-light module assembling.

The current R&D activities have access to two advanced processes. The TowerJazz 0.18 μm quadruple-well process enables the full CMOS pixel circuit, while LAPIS 0.2 μm double-SOI process has properly solved the crosstalk between sensor and digital part, and improved TID tolerance significantly.

In order to exploit the potential of these new developments, two design teams have started chip designs using HR CMOS and SOI technologies respectively. Two designs have been submitted to the TowerJazz foundry. The first one uses simple three transistor (3T) analog amplification circuit to carry out the optimization of sensing diode and evaluate the influence of radiation damage [19]. The second one implements a well-proved rolling shutter readout as well as an innovative data-driven readout [20, 21]. Another two designs that adopt the SOI technology have also been submitted [22]. With the amplifier and discriminator integrated into each pixel, the pixel size has been shrunk to 16 μm pitch. The chip has been thinned to 75 μm successfully and an infrared laser test has shown that a single-point resolution of 2.8 μm is achievable with that pitch [12]. All the designs for current R&D are in line with the same principle of in-pixel discrimination even though each one has its own implementation. An in-pixel discriminator can reduce analog current therefore lead to reduced power consumption.

Enhancements of the TowerJazz 0.18 μm process or Lapis 0.2 μm process are possible by migrating to a smaller feature size, 0.13 μm for example, or combining with a micro-bump 3D integration process. The latter is able to attach a second layer of pixel circuit on top of the existing layer of the sensing diode and front-end circuit. The upper tier can be fully digital part that implements data-driven readout architecture, while the lower tier can be HR CMOS or SOI pixel matrix. A promising result has been demonstrated by the successful formation of 2.5 μm Au cone bump with NpD (Nano-particle deposition) technique [23]. However, the throughput needs further improvement and the thinning of sensors has to be compatible with micro-bump 3D integration.

The TowerJazz process is expected to be sufficiently radiation hard for the expected TID. An N-type plain implant has recently been added to improve the charge collection efficiency [24], which therefore will benefit the non-ionization radiation damage. In terms of SOI process, the weak point is the BOX layer of SiO_2 . Although the TID tolerance of the SOI process has been improved dramatically by the introduction of Double-SOI and

the optimization of transistor doping recipe (LDD, lightly doped drain) [11], SOI needs carefully study on the irradiation of large scale chip and of low power designs.

Sensor thinning and ultra-low material construction of modules are subject to the constraint of $0.15\% X_0/\text{layer}$. HR CMOS wafer thinned to $50\ \mu\text{m}$ is routine in semiconductor industry nowadays. SOI wafers thinned to $75\ \mu\text{m}$ with backside implant have also been demonstrated by current R&D. However, low material detector modules need to integrate mechanical support, power and signal connection, and sufficient stiffness to avoid vibration.

4.1.8 Summary

The basic concepts of the CEPC Vertex detector, including the pixel sensors specifications required by the impact parameter resolution and radiation tolerance, the low-mass mechanical design, and the detector layout, are implemented in the baseline design. It will be crucial to develop pixel sensors with lower power consumption and fast readout electronics because of continuous colliding mode and strong beam-related background. Detailed designs for mechanical supports and cooling, cabling, and power conversion are also necessary. Most of these issues will be addressed by R&D for the CEPC and by exploring synergies with experiments which have similar requirements.

4.2 Silicon tracker detector

As described in the PreCDR [25], the silicon tracker, together with the vertex detector and the TPC (Time Projection Chamber, see Section 4.3), forms the complete tracking system of CEPC. With sufficiently low material budget to minimize the multi-scattering effect, the silicon tracker provides additional high-precision hit points along trajectories of charged particles, improving tracking efficiency and precision significantly. In addition to complementary tracking, it also provides the following functionalities:

- monitoring possible field distortion in the TPC,
- contributing detector alignment,
- separating events between bunch crossings with relative time-stamping,
- potentially dE/dx measurement.

The transverse momentum resolution can be parameterized as [26]

$$\sigma_{1/p_T} = a \oplus \frac{b}{p \sin^{3/2} \theta} \quad [\text{GeV}^{-1}] \quad (4.2)$$

with p and p_T in GeV , θ the polar angle, a in GeV^{-1} and b a dimensionless number. The two terms characterize tracking resolution and multiple scattering effect separately. If a track is measured at N points equally distributed along the trajectory, we have

$$a = \frac{\sigma_{\text{SP}}}{0.3BL'^2} \sqrt{\frac{720}{N+4}}$$

where B is in tesla, σ_{SP} in meter is the measurement resolution of each point and L' in meter is the projected length of the track onto the transverse plane. For multiple scattering

and for relativistic particles, namely $\beta = 1$, there is

$$b = 0.053 \frac{1}{BL'} \sqrt{\frac{L'}{X_0}}$$

where X_0 is radiation length in units of length.

The CEPC physics requirements put required performance on a tracker as

$$a \sim 2 \times 10^{-5} \text{ GeV}^{-1} \quad \text{and} \quad b \sim 1 \times 10^{-3}. \quad (4.3)$$

At low momenta, less than 50 GeV for perpendicular tracks, the resolution is dominant with the multiple scattering effect, and at high momenta, the resolution approaches to the tracking resolution, in turn determined by the single-point resolution. Hence, stringent constrain has to be put on material budget.

4.2.1 Baseline design

The main characteristic of the baseline design for the CEPC silicon tracker is a silicon envelope [27] around the TPC. It consists of four components: the Silicon Inner Tracker (SIT), the Silicon External Tracker (SET), the End-cap Tracking Detector (ETD) and the Forward Tracking Detector (FTD). The overall layout is shown in Figure 4.6, and the main parameters are summarized in Table 4.4.

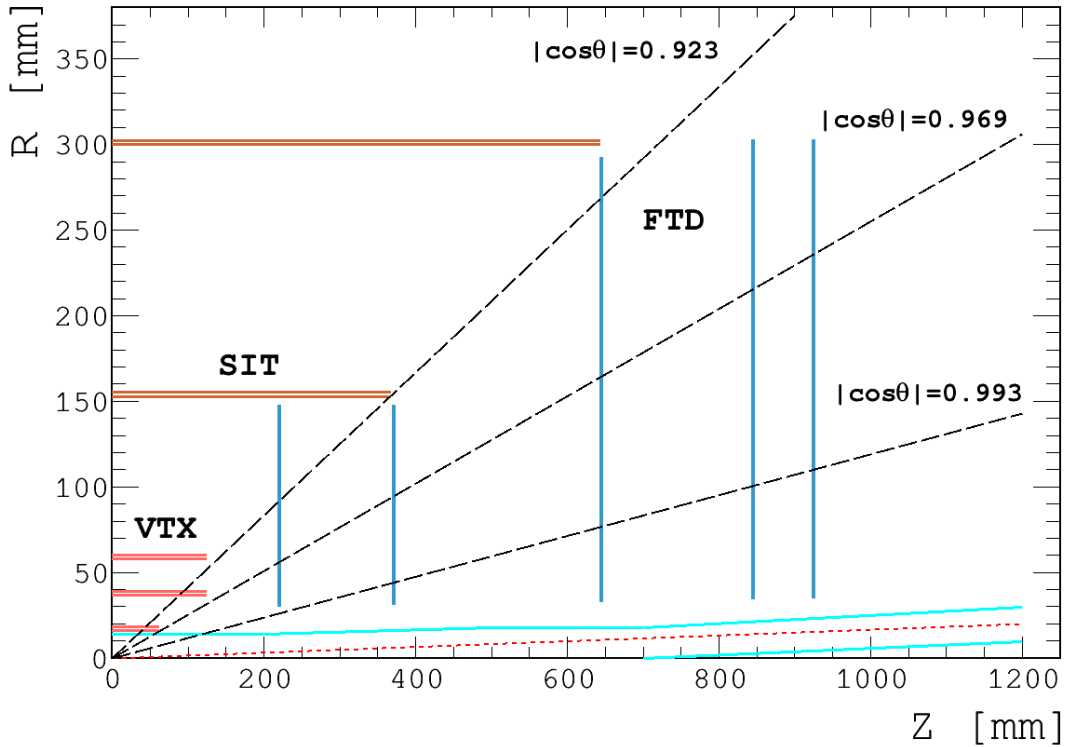

Figure 4.6: Preliminary layout of the CEPC silicon tracker. The red lines indicate the positions of the vertex detector layers and the blue lines the SIT and FTD for the silicon tracker. The SET and ETD, which sit outside the TPC, are not displayed.

Detector		Geometric dimensions			Material budget [X/X_0]
SIT	Layer 1:	$r = 153$ mm,	$z = 371.3$ mm		0.65%
	Layer 2:	$r = 300$ mm,	$z = 664.9$ mm		0.65%
SET	Layer 3:	$r = 1811$ mm,	$z = 2350$ mm		0.65%
FTD	Disk 1:	$r_{in} = 39$ mm,	$r_{out} = 151.9$ mm,	$z = 220$ mm	0.50%
	Disk 2:	$r_{in} = 49.6$ mm,	$r_{out} = 151.9$ mm,	$z = 371.3$ mm	0.50%
	Disk 3:	$r_{in} = 70.1$ mm,	$r_{out} = 298.9$ mm,	$z = 644.9$ mm	0.65%
	Disk 4:	$r_{in} = 79.3$ mm,	$r_{out} = 309$ mm,	$z = 846$ mm	0.65%
	Disk 5:	$r_{in} = 92.7$ mm,	$r_{out} = 309$ mm,	$z = 1057.5$ mm	0.65%
ETD	Disk:	$r_{in} = 419.3$ mm,	$r_{out} = 1822.7$ mm,	$z = 2420$ mm	0.65%

Table 4.4: Main parameters of the CEPC silicon tracker.

The barrel components SIT and SET provide precise hit points before and after the TPC, improving the overall tracking performance in the central region. The SIT helps the link between the vertex detector and the TPC, enhancing the reconstruction efficiency, particularly for low-momentum charged particles. The SET sits between the TPC and the calorimeter and helps in extrapolating from the TPC to the calorimeter. In addition, the good timing resolution of silicon sensors provides time-stamping for bunch separation.

The ETD is positioned in the gap between the endplate of the TPC and the end-cap calorimeter. It helps to reconstruct charged particles with a reduced path in the TPC. The SIT, SET and ETD covers the central tracking region. They form the complete silicon envelope and help in calibrating the tracking system.

The FTD is installed between the beam pipe and the inner cage of the TPC, covering the very forward region. It consists of five silicon disks on each side. The FTD is essential for precise and efficient tracking down to very small (or large) solid angles, where a number of challenges exist: the magnetic field approaching zero along the beam pipe, significantly larger occupancies due to forward going jets and high backgrounds from the interaction region. To achieve the best tracking performance, the FTD needs precise space points, a large lever arm, but low material budget. The baseline design would be a compromise among the constraints. Using highly granular pixel sensors for the first two disks can be foreseen to lower the occupancy and improve the $r\phi$ resolution.

4.2.2 Sensor technologies

The basic sensor technology is silicon microstrips for all tracker components except the two innermost FTD disks where silicon pixels are foreseen. Requirements of the single point resolution vary with positions of tracker components, but a general condition of $\sigma_{SP} < 7 \mu\text{m}$ is required for high precision tracking. The microstrip sensors have proven to be capable of the resolution, taking into account material budget and power consumption. The baseline features of microstrip sensors will be a large detection area of $10 \times 10 \text{ cm}^2$, a fine pitch of $50 \mu\text{m}$ and the thickness $< 200 \mu\text{m}$ to minimize the multi-scattering effect.

The alternative is a fully, or at least for inner components, pixelated silicon tracker. Although the choice of pixel technologies is open, the CMOS pixel sensors (CPS) have

gained particular interest. The main advantages of the CPS comparing to the microstrip sensors are two folds:

- Granularity. The CPS provides better single-point spatial resolution and significantly reduces the ambiguity caused by multiple hits in a single strip.
- Material budget. The CPS can be thinned to less than 50 μm , whereas the strip sensor is usually a few hundred microns.

As for the cost, because the CPS is based on the standard CMOS procedure in industry, production cost could be significantly reduced for fabricating large area sensors. In addition, the size of pixels used for the tracker can be comparatively large, hence it's possible to embed complicated circuits in the pixel to simplify the tracker readout circuitry. Initial R&D on large area CPS has been carried out.

Table 4.5 estimates the pixel occupancy of SIT-L1 and FTD-D1. There are a few assumptions in the estimation.

1. The pixel dimension is assumed to be $50\text{ }\mu\text{m} \times 350\text{ }\mu\text{m}$, with which at least in one dimension spatial resolution can reach $7\text{ }\mu\text{m}$ by implementing in-pixel ADC with multiple bits.
2. The track multiplicities in different operation modes are inferred from hit densities in Table 9.4.
3. Readout time of pixel sensors is set as $20\text{ }\mu\text{s}$, the same as that of VTX.
4. Cluster size is set as 9 hits per track.

Table 4.5: Pixel occupancy of SIT-L1 and FTD-D1. See context for explanations.

operation mode	H (240)	W (160)	Z (91)
track multiplicity (BX^{-1})	310	300	32
bunching spacing (ns)	680	210	25
SIT-L1 occupancy (%)	0.19	0.58	0.52
FTD-D1 occupancy (%)	0.17	0.54	0.48

4.2.3 Front-End electronics

The Front-End (FE) electronics will depend on the choice of sensor, namely microstrips or pixels.

For the microstrips, custom designed ASICs with deep sub-micron CMOS technology will be used. The chips will provide functions of the analogue to digital conversion (ADC), zero suppression, sparcification and possibly time stamping, together with necessary control circuitry. The high degree digitization is for relaxing the data processing pressure on downstream electronics.

As for the pixels, all FE functions can be realized in a pixel chip, even with some functions, e.g., ADC on pixels themselves. Particular concerns are readout time and electronic channels.

Commonly, the FE chip will be developed in mind with low noise, low power consumption and high radiation tolerance. New developments, such as in the SiLC collaboration and the LHC experiment upgrades, will be good references.

4.2.4 Powering and cooling

Powering and cooling are a challenge for the CEPC silicon tracker. It is important to investigate the novel powering scheme based on DC-DC converters, which has been already actively pursued by the ATLAS and CMS experiments for silicon detector upgrades [28–30]. It allows significant reduction in material budget for the low-voltage power cables and gives less power dissipation in the delivery system. Cooling is another critical issue. Although cooling based on forced cooled gas flow might be still feasible to efficiently conduct away the heat generated by the sensors, ASICs and other electronics, it is important to look into other cooling techniques, such as silicon micro-channel cooling [31], which are being investigated by several other experiments. The technique chosen will have to provide sufficient cooling without compromising the detector performance.

4.2.5 Mechanics and integration

There will always be additional challenging aspects of the mechanical design for a large area silicon tracker. A lightweight but stiff support structure can be built based on Carbon fibre Reinforced Plastic material [32]. The support structure, cable routing and electronics common to other sub-detectors need to be carefully designed to minimize the overall quantity of material and make easy construction and integration possible. Precise and quick system alignment might be achieved with dedicated laser monitoring systems, while the final alignment will be accomplished using tracks from well-understood physics events [33].

4.2.6 Silicon tracker performance

The performance study described in the section is based on the vertex detector and the silicon tracker.

While the tracking performance in the central region has been extensively studied, the performance in the forward region, which has been designed to cope with the rather short L^* , requires additional careful evaluation. Figure 4.7 shows the estimated transverse momentum resolution for single muon tracks for two polar angles $\theta = 20^\circ$ and 85° , and the analytical results from Eq. (4.2) and Eq. (4.3). Due the reduced lever arm of the tracks and fewer FTD disks in the forward region ($\theta = 20^\circ$), the resolution is worse than the required performance.

Tracking performance of the alternative pixelated silicon tracker has been studied with fast simulation, in which the microstrips are replaced with double-sided pixels with certain single point resolution and material budget reduced to $0.3\%X_0$, the same as VTX. Figure 4.8 shows the transverse momentum resolution for single muons with fixed momentum as a function of polar angle, comparing the pixelated tracker with various single point resolutions to the baseline microstrip tracker. Significant improvement can be observed when the polar angle is below about 20° , in the tracking region of FTD. There is no, however, obvious difference for chosen pixel resolutions, all less than $10\mu\text{m}$.

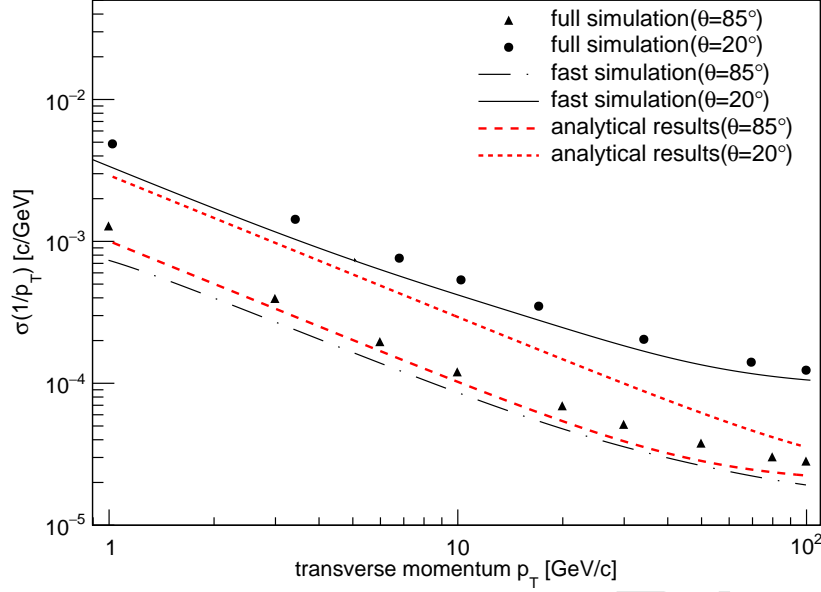

Figure 4.7: Transverse momentum resolution for single muon tracks as a function of the track momentum estimated for the CEPC baseline design with full simulation (dots) and fast simulation (black lines) compared to the analytical results obtained with Eq. 4.2 (red lines).

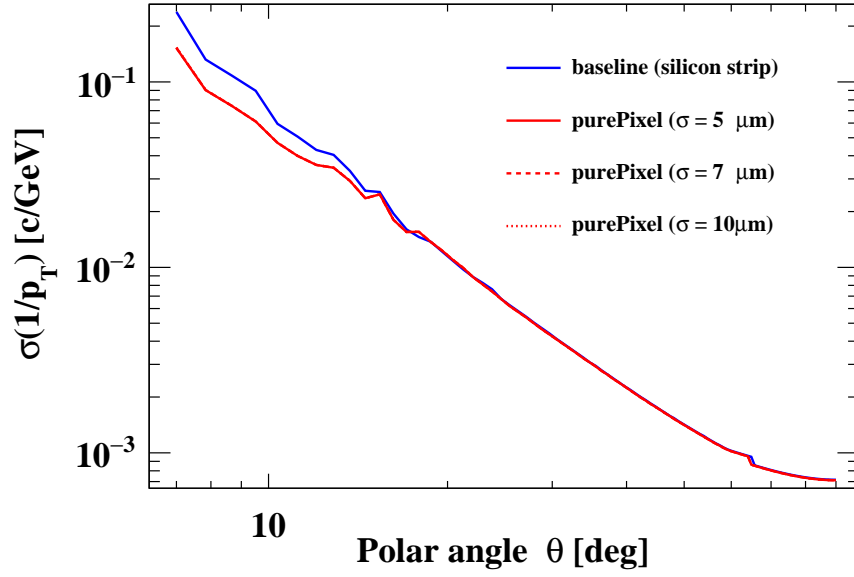

Given the importance for heavy-flavor tagging, the impact parameter resolution, both transverse and longitudinal, is assessed, as shown in Figure 4.9 with muon momentum of 10 GeV. Similar improvements can be observed, even in the high momentum range for the longitudinal impact parameter.

Further comparison is made for tracks at a fixed forward polar angle, 10° , which pass all five FTD disks, as shown in Figure 4.10. Significant improvements can be observed in the whole momentum range for resolutions of transverse momentum and transverse impact parameter. As for longitudinal impact parameter, there is only slight improvement for high momenta, that is understandable because the z -resolution mainly depends on disk positions.

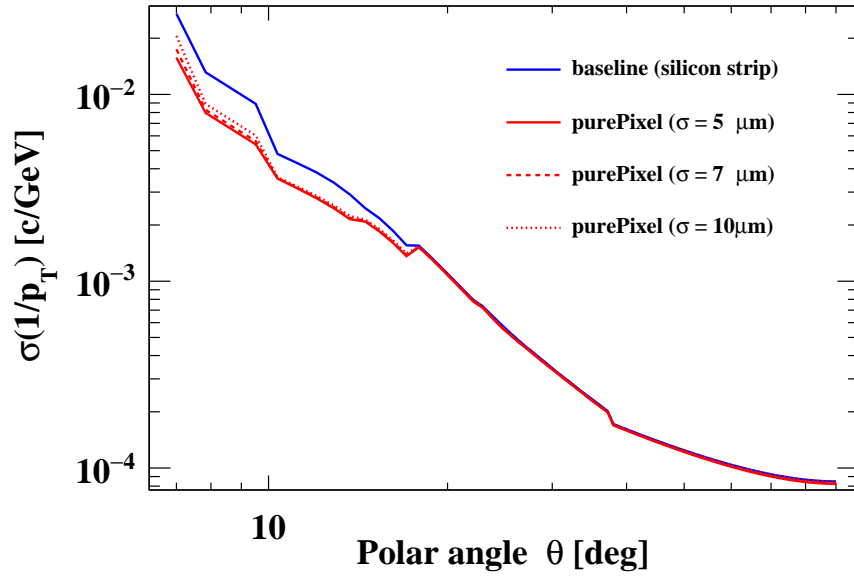

The studies are quite preliminary. There are spaces to optimize the performance of the pixelated tracker, particularly the pixel layout of FTD disks. Some other preliminary studies on the resolution of transverse impact parameter can be found in PreCDR [25].

4.2.7 Critical R&D

Silicon technology for large-area tracking detectors will continue to evolve over the next few years [34]. There are ongoing R&D activities conducted by the ATLAS and CMS experiments to develop advanced silicon detectors for the High Luminosity LHC as well as several pioneering R&D projects by the SiLC (Silicon tracking for the Linear Collider) collaboration. Despite the rather different operation conditions and requirements, it is always important to exploit synergies with existing R&D from other experiments to share expertise. During the preliminary studies, several critical R&D items have been identified for the CEPC silicon tracker. All of them, as listed below, will be pursued in the R&D phase of the CEPC project and made available for engineering construction.

(a) $p = 1 \text{ GeV}$

(b) $p = 10 \text{ GeV}$

Figure 4.8: Transverse momentum resolution for single muons with momentum of $p = 1 \text{ GeV}$ (a) and $p = 10 \text{ GeV}$ (b) as a function of polar angle, obtained for the baseline CEPC silicon tracker with microstrips (in blue) and for pixelated tracker (purePixel) with various single point resolutions (in red).

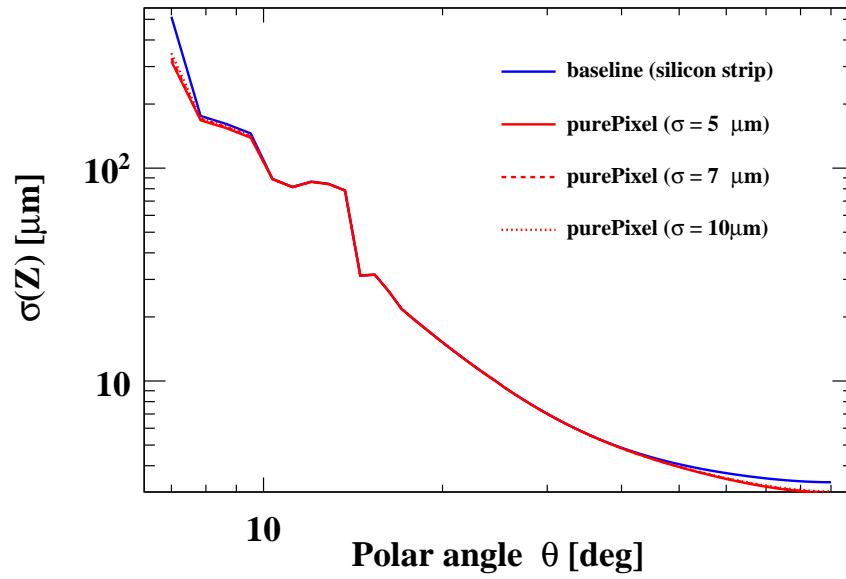

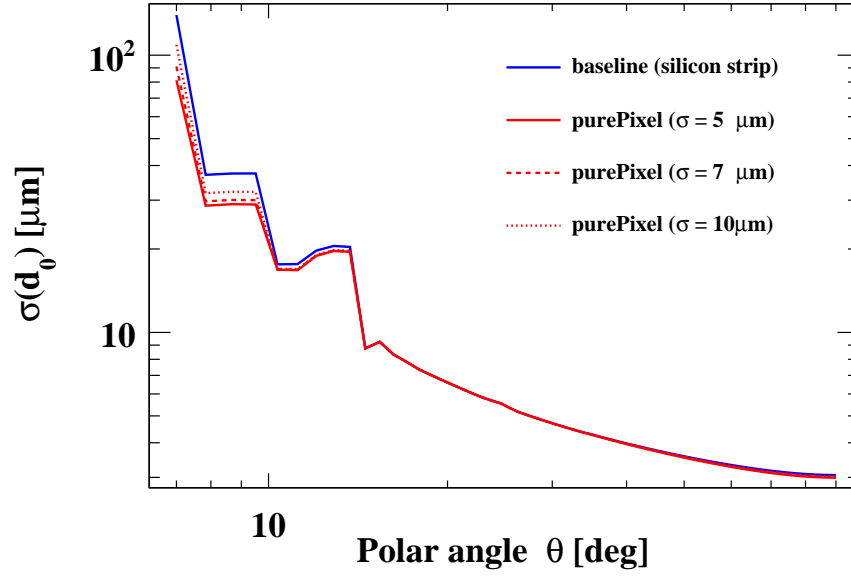

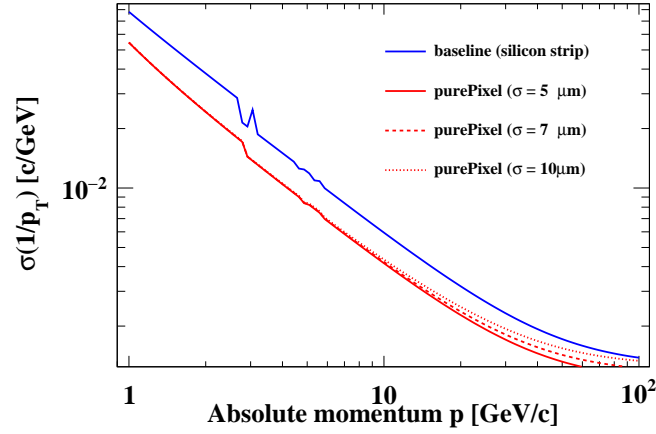

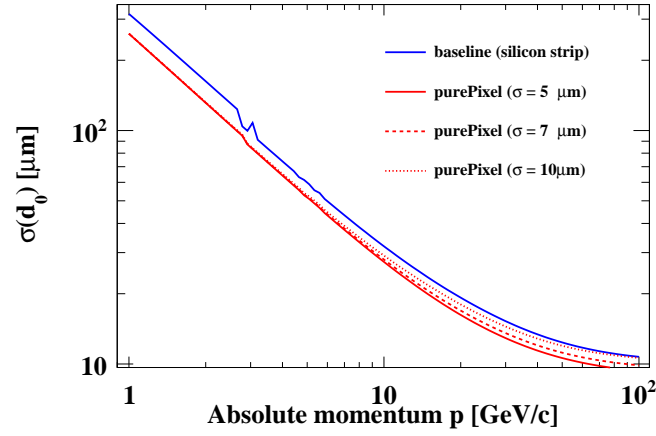

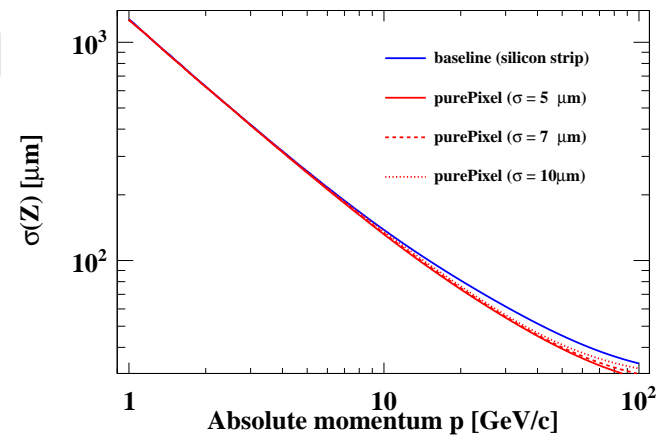

Figure 4.9: Transverse (a) and longitudinal (b) impact-parameter resolution for single muons with momentum of $p = 10$ GeV as a function of polar angle, obtained for the baseline CEPC silicon tracker with microstrips (in blue) and for pixelated tracker (purePixel) with various single point resolutions (in red).

(a) σ_{1/p_T}

(b) σ_{d_0}

(c) σ_z

Figure 4.10: Transverse momentum (a) and transverse (b) and longitudinal (c) impact-parameter resolution for single muons with the polar angle of 10° as a function of the track momentum, obtained for the baseline CEPC silicon tracker with microstrips (in blue) and for pixelated tracker (purePixel) with various single point resolutions (in red).

- Alternative pixelated strip sensors with CMOS technologies;
- p^+ -on-n silicon microstrip sensors with slim-edge structure;
- Front-end electronics with low power consumption and low noise, fabricated with CMOS technologies of small feature size;
- Efficient powering with low material budget and CO₂ cooling techniques;
- Lightweight but robust support structure and related mechanics;
- Detector layout optimization, in particular in the forward region.

It will be vital to develop necessary instrumentation for the module assembly and to verify the detector module performance with beam tests. Prototypes of support structures, including cooling solutions, shall be also built for mechanical and thermal tests.

4.3 TPC tracker detector

Time Projection Chambers (TPCs) have been extensively studied and used in many fields, especially in particle physics experiments, including STAR [35] and ALICE [36]. Since the tracking system are expected to affect the translation of the trackers as less as possible, which require it to be as light as possible. The particle ID ability is one of the feasibility of the tracking system, however for such energetic tracks, the classic method, such as dE/dx , TOF are not reliable, so that the TPC could be used as a primary central tracker [37] [38]. In CEPC, the inner tracking system should be sensitive in momentum measurement to charged particles, which transverse momentum ranged from 0 to 80 GeV, furthermore, the accelerator with precision appropriate to the energy uncertainty of a beam [39]. Their inexpensive material budget and excellent pattern recognition capability make them ideal for three-dimensional tracking and identification of charged particles. They are also the exclusive type of electronically read gaseous detector delivering direct three-dimensional track information. Nevertheless, there has always been a critical problem with TPCs, especially in high background conditions, the space charge distortion due to the accumulation of positive ions in the drift volume [40].

TPC will be as a part of the detector concepts for the CEPC, and it can measure the momentum of tracks of charged particles in the magnetic field. Micro Pattern Gas Detector (MPGD) such as Gas Electron Multiplier (GEM) and Micro-MESH Gaseous Structure (Micro MEGAS) or the Timepix chip is a candidate for the readout technology [37]. Used the MPGD as readout, the $r\phi$ position resolution could be reach to 100 μm , even it is better in the vast magnetic field (3.0T) [41]. Also, the TPC can reconstruct and identify particle species using energy loss (dE/dx) measured by the readout pad rows. In the reaction event of the electron-positron annihilation in the CEPC experiment, it is required to identify charged particle species such as pion, kaon, electron, etc. and to reconstruct the events. For the CEPC-TPC, expected dE/dx resolution is less than 5% for clear identification.

Understanding the properties and achieving the best possible point resolution have been the object of *R&D* studies of Micro-Pattern Gas Detectors, GEM, MicroMEGAS, and pixel, and results from many years work in LC-TPC international collaboration group [42].

For improving on the performance, optimising readout module and controlling ion back-flow effectively in the circular machine (CEPC), these studies will continue for the next few years in order to understand and solve several critical technology challenges.

4.3.1 Principle of Time Projection Chamber

A TPC customarily consists of a cylindrical drift volume with a central cathode and an anode at the two endplates. In the case of a colliding experiment, the TPC contains an inner radius in which the beam pipe and inner detectors are placed.

The anodes are at ground, while the cathode is at a potential high voltage to keep the range of from 100V/cm to 1000V/cm in drift length. The walls of the volume are the field cage, which ensures a highly homogeneous electrical field between the electrodes. The magnetic field is parallel to the electric field to suppress transverse diffusion. The reason for the magnetic field is that if there is no magnetic field, diffusion will dominate, degrading the track and momentum reconstruction. The electrons are released after the ionisation of the sensitive gas volume and drift along the electric field to the anodes, while the ions drift toward the cathode. An amplification device is placed in front of the anodes and creates an electron avalanche as the readout (GEM, MicroMEGAS or others).

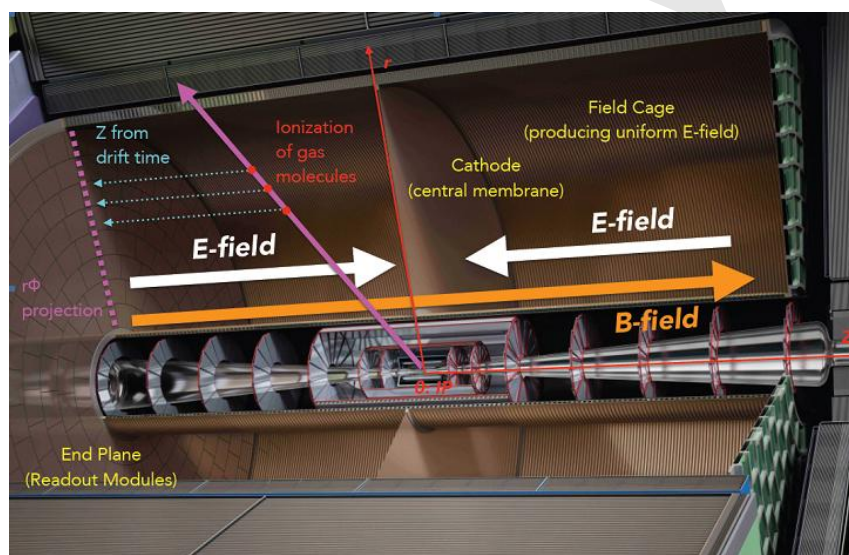

Figure 4.11: Sketch of the TPC structure.

All of TPC will be included some parts:

1. Chamber TPC chambers are typically cylindrical and operate under the atmospheric pressure with the working gas filled inside. Chambers in high magnetic field close to the centre of the magnet, usually have a higher occupancy due to the curling low-energy tracks. Hence the material budget of stations inside the magnet is kept as inexpensive as possible. In the active area, the added the material due to the filled gas should be less than $1\% X_0$. The chambers are attached to the end-plate from the inside to minimise the dead area between adjacent chambers. Thus, a particular mounting technique is required to enable rotation and tilting of the chambers.
2. Field cage The cylindrical chamber's inner and outer composite walls hold the field and forming strips, which are attached to a resistor divider chain network. The resis-

tors must be non-magnetic. A central cathode will be held at approximately 50 kV when the drift field is 300 V/cm, with the end-plates and the other outer surfaces of the TPC at ground potential. Therefore the composite walls must self-stand the enormous potential of the central cathode. The narrow mirror strips will be arranged between the inner and outer walls to maintain the electron field uniform in over the whole active TPC volume.

3. End-plate To obtain high position resolution, every end-plate is subdivided into many independent MPGD detector modules (GEM or Resistive/no Micromegas detector, so on), which can provide nearly full coverage of the end-plate. Power cables, electronic connectors, cooling pipes, PCB boards and support brackets wall are also mounted on the end-plate. In case the detector modules are damaged by the discharge or spark, they can be replaced, and the end-plate should be kept stable during the replacement. Besides, the end-plate needs to constructed from a lightweight material, not only compromise the jet energy resolution in the forward region but also should be still sufficiently rigid to achieve stable positioning of the detector modules with a position accuracy better than 50 μm . The material budget of the mechanical structure accounts for 8% X_0 . Additional materials for the readout planes, front-end electronics and cooling are estimated to be 7% X_0 , and power cables and the connector up to 10% X_0 .

The TPC could provide some physics information: Firstly, the function is 3-dimensional track reconstruction, by getting the XY information from the anode segmented in pads and the Z coordinate delivered by the drift time. To obtain the Z coordinate from the drift time, the drift field has to be very homogeneous. Because this coordinate is obtained via the drift velocity of the electron, it should have a moderate dependence on the drift field for a given gas mixture. Secondly, a parameter is the total momentum of a charged particle, by measuring the radius, ρ , of the electron trajectory to get the transverse momentum, and adding this information to the knowledge of the trajectory in the Z plane. The final function is the particle identification. The energy loss can be extracted by measuring the charge deposited on the readout pads. The energy loss combined with the measurement of momentum in the magnetic field provides then the particle identification.

4.3.2 Baseline design and technology challenges

4.3.2.1 Main parameters of the detector geometry

In TPC parameters, the geometry will be limited with an inner diameter, outer diameter, drift length, electric field, and the magnetic field. The transverse momentum resolution Δp_t of a tracking device - one of the basic figures of merit - is described by the Gluckstern formula

$$\frac{\Delta p_t}{p_t^2} \propto \frac{\sigma_{r\phi}}{BL^2} \sqrt{\frac{720}{n+4}} \quad (4.4)$$

where $\sigma_{r\phi}$ denotes the spatial single-point resolution in the $r\phi$ -plane, B is the magnetic field strength, L is the length over which the measuring points are distributed, and n is the number of single-point measurements that are used in the overall track fit.

From that formula [43], there is strong confidence that a TPC will be able to meet the performance goals of the CEPC tracker detector since it has corresponding advantages:

with a single-point resolution of $r\phi=100\mu m$, with a magnetic field of 3T, with an inner radius of 0.3m and an outer radius of 1.5-1.8m, and with approximately 200 pad rows.

The resolution of the TPC is limited by the diffusion of the drifting electrons. An upper bound on the diffusion is calculated using the standard Gluckstern parameterization, assuming a large number of measurements along the length of the track

$$D < \frac{\sigma_{pt} t}{p_t} \sqrt{\frac{n_T L}{720}} (L[m]^2) \frac{0.3B[T]}{p_t[GeV/c]} \frac{1}{\sqrt{L_{drift}}} = 100 \frac{\mu m}{\sqrt{cm}} \quad (4.5)$$

where the diffusion component of the momentum resolution (σ_{pt}/p_t) is required to be less than 10^{-4} at $p_t=1GeV/c$, $n_T=30$ ionization electrons per cm of gas (mainly argon) for a track measured over $L=1.8m$ and for a drift distance of $L_{drift}=2.0m$ in the magnetic field of 3.0T [44].

A large volume TPC with about 200 points per track provides continuous tracking for a large volume (several meters level). The TPC is optimised for superb three-dimensional point resolution and minimum material in the field cage and the end plate. It also provides particle identification capabilities based on the energy loss of particles per unit of distance (dE/dx). The geometry baseline should be considered the following reasons: Sensitive to the track segment as long as possible, stronger enough magnetic field for track bending and as good as possible and position resolution of the track measurement.

4.3.2.2 Modularization design

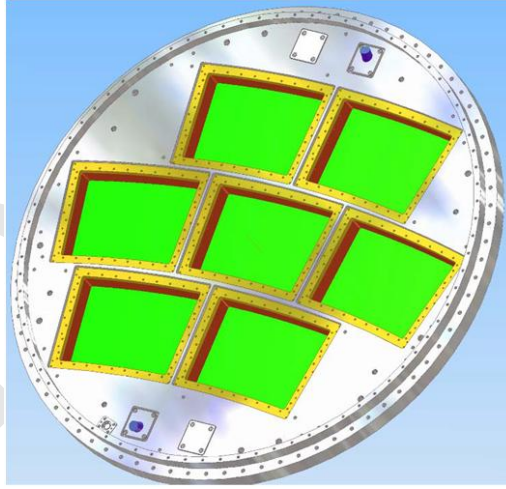

Figure 4.12: The diagram of large prototype module design.

In the large collider machine, the readout structure is designed to be modularised to change and maintain readily. Each module will consist of gas amplification system, read-out pad plane and following electronics. High-density electronics make it possible to integrate the electronics directly on the back of the readout pad plane. The readout module will then have to provide all necessary high and low voltages and cooling for heat dissipation, notwithstanding, mainly because power-pulsing will not be available at the CEPC. To achieve the required performance, an MPGD-based gas amplification system will be developed. The charge from the amplification system will be collected on a pad board. Each module size will be about 160mm-180mm of width and 190mm-210mm of height.

The figure 4.12 shows that the diagram of large prototype module design in LC-TPC international collaboration group *R&D*.

To satisfy the physics performance basing on the modularisation design, it has been demonstrated that any amplification technologies combined with pad readout can be built as modules which cover large areas with little dead space.

4.3.2.3 Gas amplification detector module

Typically gains of $10^3 - 10^4$ are achieved with many gases under standard conditions. Gas Electron Multipliers[45] and MICRO-Mesh device[46] of the (MPGDs) detectors[47] have been developed for the high energy physics experiments. For the detector modules, the electron gas amplification is obtained in very high fields generated by modest voltages (300-400V) across $50 - 100\mu m$ structures suitable for large-area applications. Gaseous structure are two example of MPGDs.

This gas amplification detector module for a pad-based TPC will be either GEM, MicroMEGAS or others structure since single of them do not satisfy the ambitious performance purposes. Two or three GEMs are stacked together to achieve sufficient charge amplification resistive MicroMEGAS have enough amplification in a single structure.

Micro-pattern devices for TPC provide in the e^+e^- collider machine:

1. Higher rate capability: MPGDs provide a rate capability over $10^5 Hz/mm^2$ without the discharge to protect the electronics.
2. Intrinsic ion feedback suppression: The ions produced on these field lines do not go back to the drift volume and most of them will be neutralised on the mesh or GEM foil.
3. A direct electron signal, which gives a better time resolution ($-100\mu m$).
4. A larger gain, by the specific operation high voltage.
5. Much smaller $E \times B$ effects than wires chamber for which the spacing of the wires is about a few mm.

4.3.2.4 Optimization readout pad size

Design of readout pad size is a vital parameter for the TPC detector module whether using GEM, MicroMEGAS or combination structure as the readout detector. Accurate position information requires to process the adjacent pad's signal with the Center-of-Gravity Method (CGM).

The design of the two-dimensional readout strips has been developed with the triple GEMs of $100mm^2$ in IHEP. The readout strips in the X direction are $193\mu m$ wide at $752\mu m$ intervals. There are pads with a size of $356\mu m \times 356\mu m$ connected with each other in the Y direction, and their strip pitch is $457\mu m$. The difference in strip widths is to improve signal sharing between X-axis and Y-axis strips, to ensure a homogeneous charge distribution between adjacent strips. The total number of strips in X and Y directions are 267 channels and 437 channels respectively. Each strip is connected to one electronic channel to process the signal.

In the figure 4.13 of the typical profile of the electrons cluster in readout strips, the pink circle could be move to the blue circle and the profile is the Gaussian distribution. If there is a enough number pads to use Center-of-Gravity Method, the pad width should

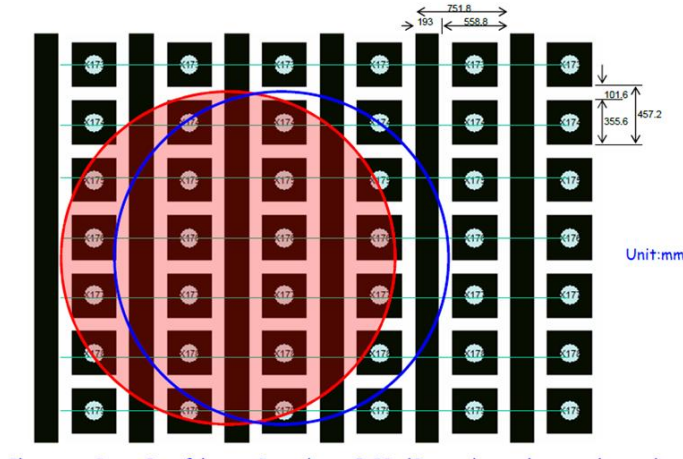

Figure 4.13: The profile of the electrons cluster in Triple GEMs.

be designed to 1.0mm and the length of pad should be designed to 6.0mm to obtain the sufficient charge information when the amplifier gain is 10mV/fC.

4.3.2.5 Operation gas for the long drift

As with any gaseous detector, the choice of the chamber gas strongly affects the properties and eventually the performance of a TPC. Desirable characteristics are:

1. Higher drift velocity (to avoid accumulation of too many events inside the chamber)
2. A very low transverse and a low longitudinal diffusion coefficient (to prevent deterioration of the spatial resolution)
3. A sufficiently large specific energy loss dE/dx
4. A high enough stability against electrical breakdowns (to allow reliable operation of the amplification device)
5. Nonhazardous chemical properties (to address safety concerns like in-flammability and damages to the hardware)

The gas mixture should be chosen to minimize the capture of electrons by the molecules of electronegative impurities. Due to the long drift distance of the several meters (3.0m), and the fact that ions are more massive and much slower than electrons, ions can accumulate in the chamber. This effect can lead to electric field distortions and should be avoided. To decrease this effect, the structure of the readout chambers is generally designed to avoid ions from escaping into the gas volume. A gas with a large drift velocity is also chosen in experiments with large interaction rate.

In given the working gas and the electric field, the drift velocity of electron could be determined with Eq. 4.6

$$\mu_e = f\left(\frac{E}{P}\right) \quad (4.6)$$

where E denotes the electric field vector, P the gas pressure and μ_e the electron drift velocity. After reaching the maximum value of the drift velocity, the electron drift velocity depends slightly on the electric field. Fig. 4.14 shows that the drift velocity obtained in

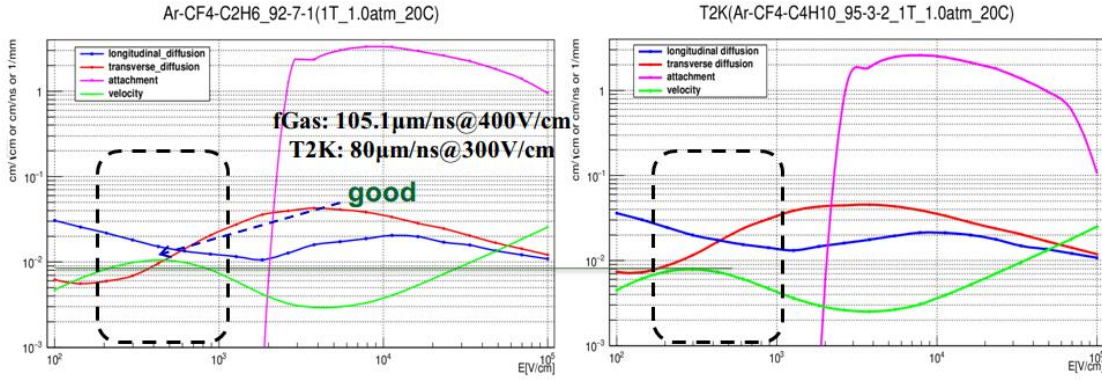

Figure 4.14: The drift velocity in different gas mixture.

different mixture gases. For the CEPC TPC detector, it is required to be sensitive to as long as possible track segment. The working gas should be selected in such way to achieve high velocity in low drift field to lower the high voltage in all of the drift length, and small transverse diffusion in the magnetic field to decrease the electron cluster size on the readout pads.

The gas mixture of Ar/CF₄/iC₄H₁₀ (95%/3%/2%) have been used for the Large Prototype of TPC Detector for the ILD TPC and the TPC chamber for the T2K experiment. The saturated drift velocity of the mixed gas reaches approximately 8 cm/μs in a drift field of 300 V/cm. In addition, the gas has a large parameter of $\omega\tau$ (same as the Eq. 4.6) and transverse diffusion coefficient of 30 μm/√cm in the drift field of 300 V/cm. In the B -field, a reasonable transverse diffusion coefficient could be realized at 100 V/cm of the drift field. The bunch spacing at the CEPC is ~ 3.6 μs (the preliminary example beam structure parameter). The working gas has a higher saturated drift velocity than the T2K mixed gas should be considered. Besides, the gas amplification requires to achieve approximately 6000 and the signal attenuation of the electron attachment should be kept below 1%/m.

4.3.2.6 Low power consumption electronics readout

Small readout pads of a few square millimeters (e.g. $1\text{mm} \times 6\text{mm}$) are needed to achieve high spatial and momentum resolution in TPC, demanding about 1 million channels of readout electronics per endcap. The total power consumption of the front-end electronics is limited by the cooling system to be several kilo-watts in practice, and they have to work continuously in CEPC. Hence the technique of so-called power pulsing cannot be applied. The architecture of the TPC readout electronics is shown in Fig.1, selected from a broad range of survey on current electronics installed or under development during past decades, including ALTRO/S-ALTRO and more recently SAMPA for ALICE, AFTER/GET for T2K and Timepix for ILC. It consists of the front-end electronics on the detector panel and the data acquisition system several meters away from the detector.

The waveform sampling front end is preferable, including a preamplifier and a shaper as the analog front-end (AFE), a waveform sampling ADC in 10MSPS, a dedicated digital signal processing (DSP) and zero-suppression unit and a de-randomize event buffer for each channel. To satisfy the stringent requirements on the integration and the power consumption, a front-end ASIC will be developed in advanced 65nm CMOS process. The key specifications of the front-end ASIC are summarized in Table as follow.

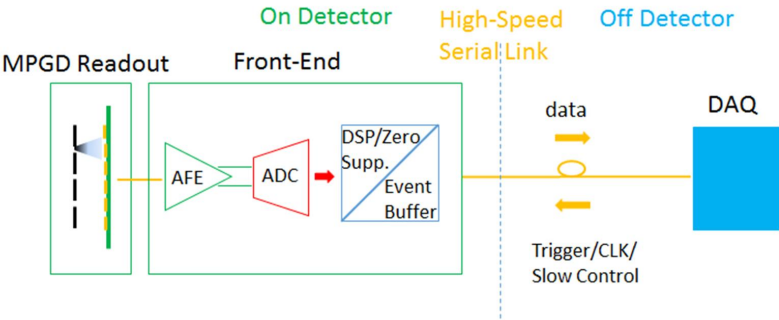

Figure 4.15: The architecture of the TPC readout electronics.

Total number of channels		1 million per endcap
APE	ENC	500e@10pF input cap
	Gain	10mV/fC
	Shaper	CR-RC
	Peaking time	100ns
ADC	Sampling rate	$\geq 20MSPS$
	Resolution	10 bit
Power consumption		$\leq 5mW$ per channel
Output data bandwidth		300MB-500MB
Channel number		32
Process		TSMC 65nm LP

Table 4.6: TPC readout electronics.

CMOS scales down in favor of digital circuits regarding power and density. The power consumption of the DSP circuits reported in *Ref.*[3] was $4mW/ch$ in a 130nm process and could be reduced by a factor of at least two by migrating the same design to 65nm. However, this is not the equivalent of the analog circuits. The design strategy for the front-end ASIC is to keep the analog part as simple as possible. The block diagram of the analog front-end and the successive approximation (SAR) ADC are shown in Fig.2 and Fig.3 respectively. The CR-RC shaper and the SAR ADC instead of pipeline ADC will be used for their simplicity in analog circuits and hence the higher power efficiency, hence the development of the low power front-end ASIC is essential.

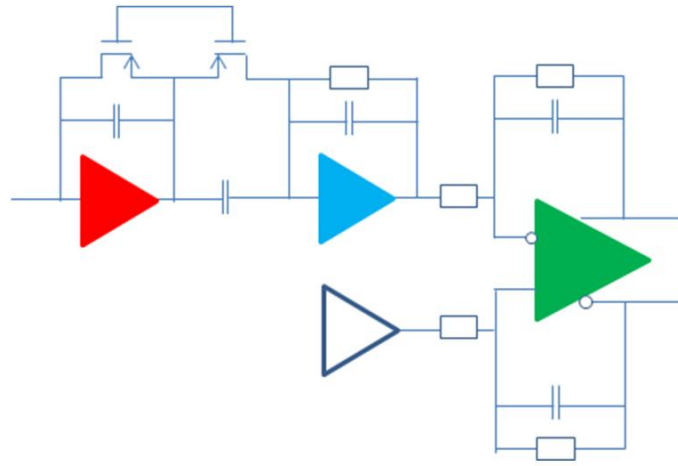

Figure 4.16: The block diagram of the analog front-end.

Dedicated digital filters will be applied to the continuously digitized input signals to suppress the pedestal perturbations caused by the non-ideal effects such as temperature variation and environmental disturbance. Then the data will be compressed by only storing the data packets above a programmable threshold with a specified number of pre- and post-samples. A data head will be added to each packet with its timestamp and other information for reconstruction afterward. The buffered data are readout through high-speed serial links to the DAQ system. The front-end electronics can support both external trigger and self-trigger mode.

Even with the state of the art technology, the TPC front-end electronics on the endplate needs cooling system to keep the temperature stable. Two-phase CO_2 cooling[7] is a well-developed technology and can be used as a baseline solution to bring out the heat generated by the front-end electronics and to keep the temperature of the TPC chamber stable at 20°C. Micro-channel CO_2 cooling has lower mass and may be studied further and can be an alternative technique to copper pipes [8].

The TPC readout electronics are meters away from the collision point, and the radiation dose is rather low ($< 1krad$) at CEPC, which allows us to use standard, radiation soft technologies. On the other hand, energetic particles can always produce instantaneous failure (SEU or SEL) from time to time. Hence radiation sophisticated design needs to be considered that the overall system performance will not be affected or even irreversibly damaged by the rare events.

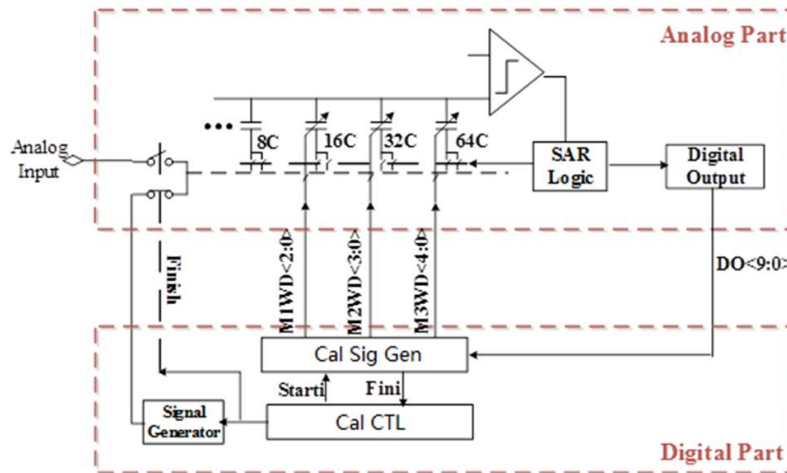

Figure 4.17: The block diagram of the SAR-ADC.

4.3.2.7 Critical technology challenges of TPC detector

The mechanical structure of the TPC consists of a field cage, which is made with advanced composite materials, and two readout end-plates that are self-contained including the gas amplification, readout electronics, supply voltage, and cooling. It will be challenging to design and manufacture the TPC support structure with a relatively light material, and at the same time very rigid. It is required to maintain accuracy, robustness in all directions, and stability over long time periods. As the field cage is not strong enough due to the limited material budget, the end-plates become the only choice, where the support structure connects to. In the current stage of design, how the TPC end-plate should be supported is not fixed yet. A promising solution is to suspend from the solenoid, in which a number of spokes run radially along the faces of the calorimeter to the TPC end-plates. A bearing is not the most challenging issue.

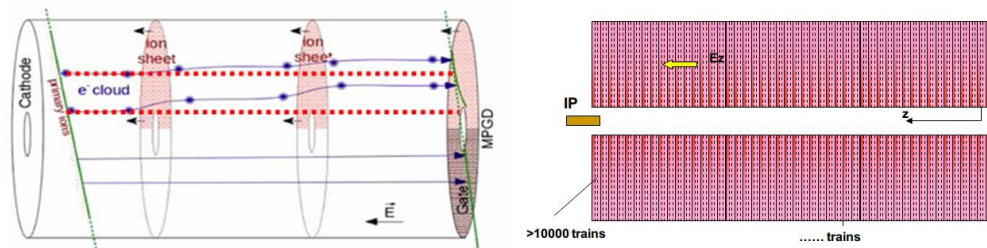

Figure 4.18: The diagram of distortion and ion disks in CEPC.

Gas amplification device creates not only secondary electrons but also the same amount of ions. These ions move in the opposite direction away from the anode region into the primary chamber volume - and furthermore have a much lower drift velocity, meaning that they could accumulate in the chamber gas and build up a significant space charge in the form of 'ion discs.' In CEPC, the majority of ions inside the drift volume are backflowing ions from the amplification region of the TPC readout devices. It is thus of

great importance to limit ion backflow (IBF) from the amplification region. This influence might affect the drifting electron tracks through electrostatic attraction as well as inhomogeneities of the drift velocity (which depends on the electric field strength). To minimize this deteriorating influence on the spatial resolution of the chamber, the backflow of ions should be suppressed.

One possible mechanism of backflow suppression frequently used together with a wire mesh device, is a so-called gating grid. The critical problem with this relatively simple yet effective scheme is that it cannot be immediately applied to the timing structure of the CEPC: the bunch spacing of the machine is so miniature ($3.6\mu s$ or less, compared to the readout time) that tracks from many events are drifting through the chamber. It indicates in the figure 4.18 of the diagram of distortion and ion disks in CEPC. Another promising option is to exploit the 'built-in' ion backflow suppression of GEMs or MicroMEGAS. In next section, the *R&D* study of the hybrid detector module has been promoted to control ions continuously, and the updated results will be described.

4.3.3 Simulation and estimation for the key issues

4.3.3.1 Occupancy requirement of Higgs and Z pole run

The CEPC is a proposed electron positron collider after the Higgs discovery. It will be applied as a Higgs factory and Z factory. As a Higgs factory, it will be operated at 240GeV center of mass energy, produce 1 million Higgs bosons in 10 years and measure the Higgs couplings to 0.1% - 1% level accuracy[48]. It will also be operated at the Z pole and produce approximately 10 billion Z bosons each year. The typical cross-sections and event rates for nominal CEPC accelerator parameters are given (Higgs runs: $2 \times 10^{34}\text{cm}^2\text{s}^{-1}$ of the instant luminosity and signal cross-section of 200fb , Z pole runs: $2 \times 10^{34}\text{cm}^2\text{s}^{-1}$ of the instant luminosity and signal cross-section of 300nb for $Z \rightarrow q\bar{q}$).

Using an sample of 9 thousand fully simulated $Z \rightarrow q\bar{q}$ events at center of mass energy of 91.2GeV [49], we studied the voxel occupancy and the local charge density of the CEPC TPC at Z pole operation for future circular electron positron colliders, with the value of an instant luminosity from $2 \times 10^{34}\text{cm}^2\text{s}^{-1}$ to $2 \times 10^{36}\text{cm}^2\text{s}^{-1}$.

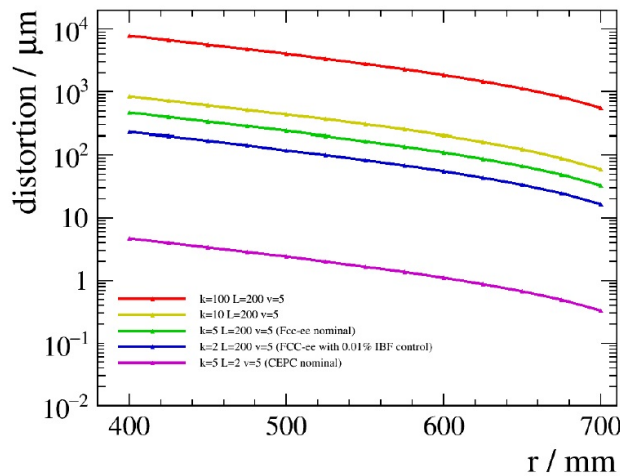

Figure 4.19: Distortion as a function of electron initial r position with different parameters.

Given the fact that the beam bunch is evenly distributed along the accelerator circumference, the voxel occupancy is extremely low ($1.4 \times 10^{-5}/1.4 \times 10^{-7}$ for the innermost layer and $3.4 \times 10^{-6}/3.4 \times 10^{-8}$ for average) and poses no pressure for the TPC usage. The distortion on TPC hit positions induced by the ion charges is estimated with dedicated program and calculation. At instant luminosity of 1×10^{36} and an ion backflow control of percent level, the distortion can be as significant as 10 mm at the innermost TPC layer at the CEPC conceptual detector geometry, which is two orders of magnitude larger than the intrinsic TPC spatial resolution.

A few approaches are proposed to reduce the effects caused by distortion:

1. Ion backflow control technology; the ion backflow should be controlled to per mille level, in other words, only 1 – 10 backflow ions are allowed for each primary ionization.
2. Dedicated distortion correction algorithm, for the innermost layers, which should result in a mitigation of the hit position distortion by one order of magnitude.
3. Adequate track finding algorithm that could link the TPC track fragments to vertex tracks at high efficiency and purity.

Taking all of these approaches account, the distortion can be mitigated by approximately the safe factors of magnitude. To conclude, the pad occupancy and distortion stress no pressure to CEPC and if the above items can be achieved.

4.3.3.2 Distortion of Ions backflow in drift length

Early TPCs were equipped with multi-wire positional chambers (MWPCs) as gas amplification devices. The IBF ratio in a standard MWPC is 30 – 40%, so a gating grid is essential to prevent ions from reaching the drift volume. In the presence of a trigger, the gating grid switches to the open state to allow ionization electrons to travel into the gas amplification region. After a maximum drift time of about $100 \mu s$ (depending on the drift length, electric field and gas mixture), the gating grid is closed to prevent positive ions from drifting back into the drift volume. Since it must remain closed until the ions have been collected on the grid wires, the ionization electrons are also blocked during this time and the dead time consequently increases.

Triggered operation of a gating grid will, therefore, lead to loss of data. Thus, the TPC at the proposed circular collider will have to be operated continuously, and the backflow of ions must be minimized without the use of a gating grid.

The ions generated from the ionisation in the drift volume or from the avalanche multiplication and have found their way into the drift region will not only introduce field distortion, but also reduce the TPC counting rate capability. This effect is called ion backflow, and should be fully suppressed in the TPC drift volume. With an averaged 300 eV required by per ion-electron ionisation and 2 keV energy loss per milli-meter, there will be roughly 12,000 primary electrons generated by a track with a typical length of 1.8 m in the TPC and there will be in total 240 k electrons in one event. With the electron drift velocity of $5 \text{ cm}/\mu s$, it takes $\sim 40 \mu s$ for all the electrons to drift 2 m to reach the end-plate. With the expected bunch spacing of $3.6 \mu s$ at the CEPC, there will be about 11 events overlapping in the TPC volume. Therefore there will be $240k \times 11/2 = 1.32 \text{ M}$ electrons continuously drifting toward the end-plate. On the other hand, ions drift much slower than electrons, with a velocity of only 500 cm/s in an electric field of 500 V/cm. This leads

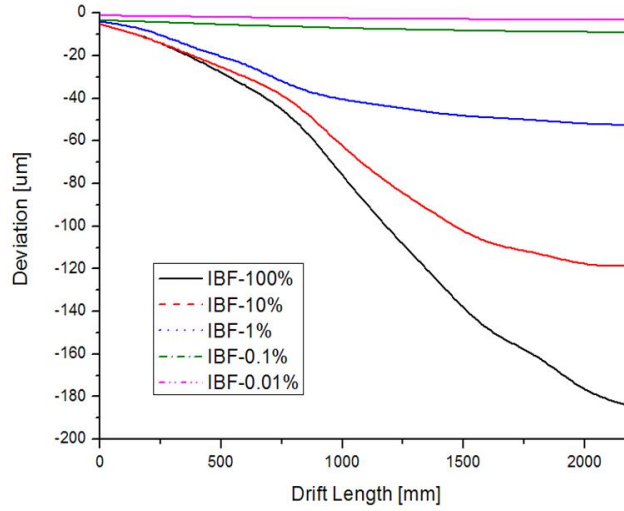

Figure 4.20: Evaluation of track distortions due to space charge effects of positive ions.

to ions from 110,000 events overlapping in the TPC volume. All of the ions should be reduce continuously.

4.3.4 Feasibility study of TPC detector module and future work

4.3.4.1 Hybrid structure TPC detector module

TPC readout with micro-pattern gaseous detectors (MPGDs), especially Gas Electron Multipliers (GEM) and micro-mesh gaseous structures (Micromegas), is very attractive, because the IBF of those detectors is intrinsically low, usually around a few percents. GEM detectors have been extensively proved in the last decade to be the prime candidate, as they offer excellent results for spatial resolution and low IBF. Numerous GEM foils can be cascaded, allowing multilayer GEM detectors to be operated at an overall gas gain above 10^4 in the presence of highly ionized particles. Micromegas is another kind of MPGD that is likely to be used as endcap detectors for the TPC readout. It is a parallel plate device, composed of a very thin metallic micromesh which separates the detector region into a drift and amplification volumes. The IBF of this detector is equal to the inverse of the field ratio between the amplification and the drift electric fields. Low IBF, therefore, favors high gain. However, the high gain will make it particularly vulnerable to sparking. The idea of combining GEM with Micromegas was first proposed with the goal of reducing the spark rate of Micromegas detectors. Pre-amplification using GEMs also extends the maximum achievable gain, so there have also been studies on gaseous photomultipliers with this hybrid configuration.

The TPC detector at the proposed circular collider will have to be operated continuously and the IBF of ions must be minimized without the open/close time of a gating device technology. The gain of the selection detector module can be achieved up to about 5000 without any obvious discharge behaviour. The currents on the anode and drift cathode were measured precisely with an electrometer. The experimental results showed that IBF can be reduced to -0.1% at the gain of about 5000.

To accomplish the physics purposes of the future circular collider, a TPC with superior performance is required. MPGDs with outstanding single-point accuracy and excellent

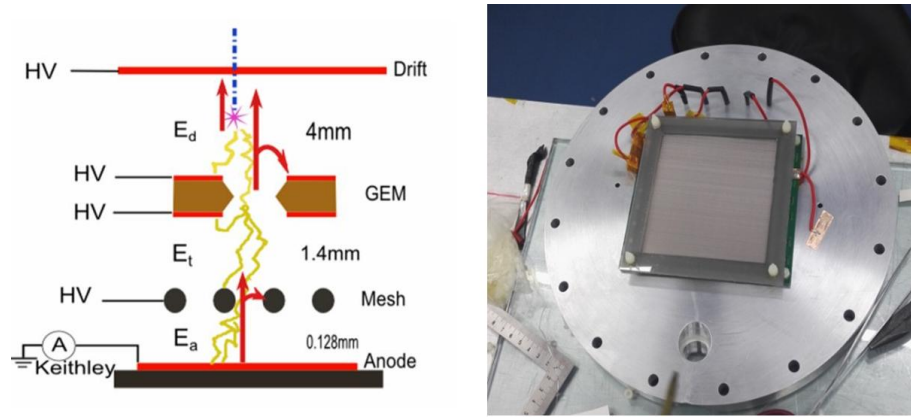

Figure 4.21: Schematic diagram of the detector module.

multi-track resolution are needed. We have proposed and investigated the performance of a novel configuration detector module: a combination of GEM and a Micromegas. The detector will be called GEM-MM for short throughout this paper. This study aims to suppress IBF continually by eliminating the gating grid. The design concept and some preliminary results of the detector module are described as following.

^{55}Fe X-ray source with a characteristic energy of 5.9 keV was used in the test. In the argon-based working gas mixture, a typically pulse height spectrum for a GEM or Micromegas detector contains one major peak corresponding to the 5.9 keV X-rays and an escape peak at lower pulse heights corresponds to the ionization energy of an electron from the argon K-shell.

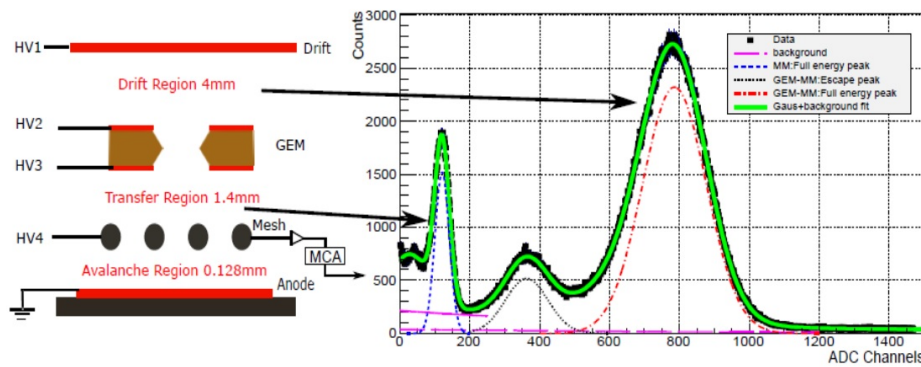

Figure 4.22: Result of the IBF TPC detector module.

In the GEM-MM detector, the situation is different. There are two amplification stages inside this detector. The primary ionization created by photon absorption can be in the drift region or in the transfer region (Figure 4.22). Photoelectrons starting from the drift region get amplified by both the GEM detector and the Micromegas detector before they are collected on the anode. If the photons are absorbed in the transfer region, the primary electrons will be amplified only once (by Micromegas).

Figure 4.22 depicts a typical ^{55}Fe pulse height spectrum obtained by the GEM-MM detector. Four peaks are seen in the pulse height spectrum. From left, the first peak and the

second peak are the escape peak and the full energy peak of the stand alone Micromegas. The last two peaks are created by photons with their energy deposited in the drift region. These primary electrons show combination amplification. The principle of the GEM-MM detector is fully verified.

Another issue should be considered that is the space charge effect to reduce the IBF value. To quantify the effect of IBF in terms of resulting space-charge distortions one can study the gas-dependent parameters as a function of the space-charge density. We make the experiment to confirm the IBF value according to the different X-ray's voltage and current.

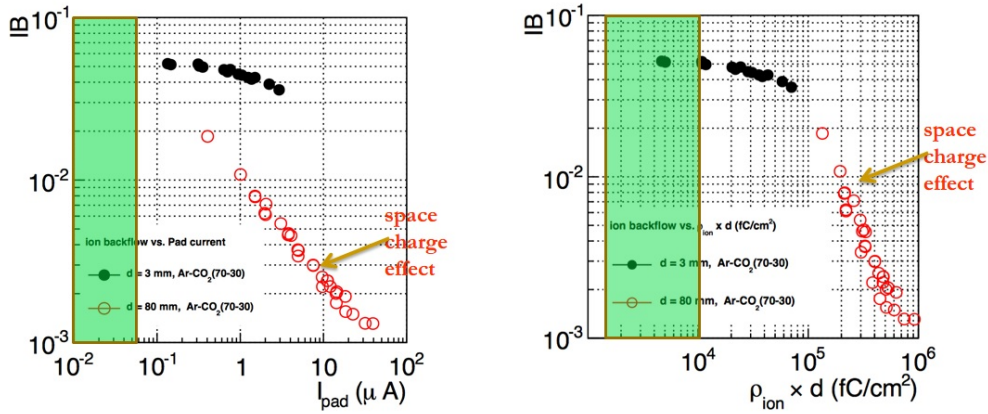

Figure 4.23: Comparison of the IBF with the different X-ray's voltage and current.

Our IBF results just obtained in the green rectangle area, there is no any obvious discharge or spark, and there is no high electrons to led the high space charge to reduce the value of IBF.

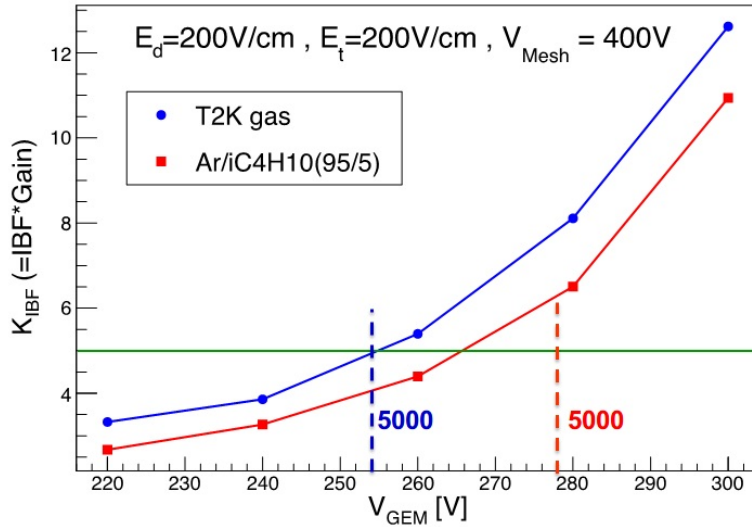

Figure 4.24: Result of the IBF TPC detector module.

A new concept in IBF reduction uses a hybrid structure with one GEM foil above a MicroMegas detector. A prototype has been built, and tests have been carried out in Ar/CO_2

(90/10) gas mixture with a ^{55}Fe X-ray source. The pre-amplification effect of GEM foil has been demonstrated in the energy spectrum measurement. With the novel hybrid structure, the effective gain of the GEM can be measured even when it is relatively low. The energy resolution of this hybrid structure gaseous detector is measured to be 27%(FWHM). The gain properties of this device were measured. A gain up to about 5000 can be achieved without any apparent discharge behavior. The currents on the anode and drift cathode were measured precisely with an electrometer. Out experimental measurements show that IBF can be reduced down to 0.19% at a gain of about 5000.

In 2018, the parameters of the electric field of drift, transfer, GEM detector and Microegas detector have been optimized testing. The key factor of the gas gain times IBF obtained at the mixtures gases of T2K and $\text{Ar}/i\text{C}_4\text{H}_{10}$ separately. The new results has been shown in the Figure4.24.

4.3.4.2 Laser calibration and alignment system

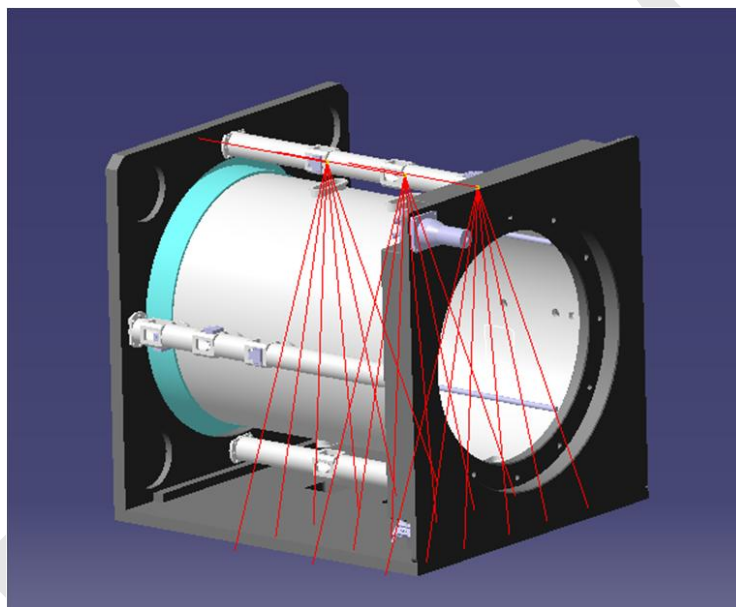

Figure 4.25: Schematic diagram of the detector module with the laser system.

The laser calibration system could be used for the TPC detector, the narrow laser beams inside the drift volume of the TPC simulate ionizing tracks at predefined locations. The goal is to obtain a uniformity of the TPC drift field within a reasonable relative error corresponding to a spacial resolution of $\sigma_{r\phi} = 100\mu\text{m}$. The system can be used for tests and calibration either outside or during normal data taking with the aim of understanding the chamber performance. Of particular interest is the testing of electronics, alignment of the read-out chambers, and measurements of variations of the drift velocity due to mechanical imperfections and non-uniformities in the gas, temperature and the electric and magnetic fields.

The laser system would be used for calibration and distortion measurement in the prototype with one module as a readout or large, A Nd:YAG laser with a wavelength of 266nm shall be used to study the track distortions. An additional UV-lamp could generate additional ions. The complete optical path and the laser power will be split into 6 – 7 laser tracks. The laser map coupling into the chamber and the planned laser tracks

could be designed. The UV laser beam for calibration and alignment purposes to monitor the drift velocity, operation gas, gain uniformity and electric field. Nd:YAG laser device with 266nm wavelength could make the ionization in the gas volume along the laser path occurs via two-photon absorption by organic impurities. The laser power should reach $10J/mm^2$ to equal 10MIP.

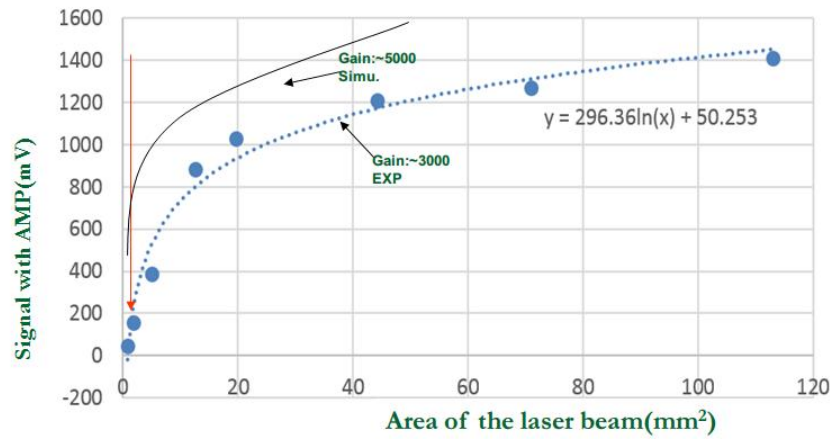

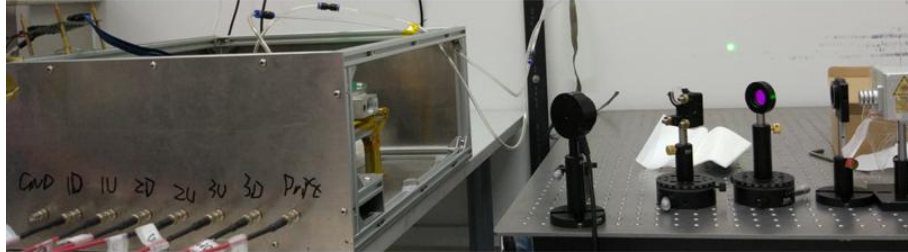

Figure 4.26: Signal with the different size of laser beam.

- Photoelectric laser source with UV light source: Enlightens the cathode with UVs could produce photoelectrons to study and monitor distortions, the cathode with UVs to produce photoelectrons to study and monitor distortions, Deuterium lamp with $160nm - 400nm$ of the wavelength as UV light source and smooth Aluminum film as a cathode. To mimic the bunch structure and the ions distortion with UV light lamp by the specific time structure shine controller, UV could create more than about 10000 $electrons/s.mm^2$.
- Calibration laser beam size: The shine and entrance window could use the fused silica as of 99% $trans.@266nm$. Provides a UV laser beam for calibration and alignment purposes to monitor the drift velocity, operation gas, gain uniformity and electric field. The ionization in the gas volume along the laser path occurs via two-photon absorption by organic impurities. The study has been done using Nd:YAG laser device has the 266nm of wavelength(4.68eV). The optimization laser beam area of the laser device will be the range from $0.8mm^2$ to $1.0mm^2$ in the figure4.26.

To solve the critical technology problems in CEPC, the hybrid structure MPGD detector module has been developed, and some preliminary results have been obtained and analyzed, the further study will be done from this combination detector module. Another small TPC prototype with 266nm laser calibration system and UV photoelectric func-

tion has been designed and would be assembled, and the calibration experiment would be further studied for CEPC.

4.3.5 Conclusion

The TPC designed following the CEPC CDR concept provides an excellent starting point for the CEPC TPC R&D, but numerous modifications are foreseen due to the different performance requirements and experimental conditions. Several critical R&D issues have been identified in pre-studies. Possible solutions to those issues have been suggested and will have to be verified with a prototype TPC in future.

Aiming for the CDR and next steps of the CEPC project, two-phase funding scheme is proposed by the funding agency, the Ministry of Science and Technology (MOST) of China. To launch the project, the MOST funded the CEPC accelerator and detector R&D project for phase-I period of 2016 – 2021. Among sub-detectors, the feasibility study of the TPC tracker detector was initiated for the purpose to identify feasible technology options and to gain expertise to build the detector units which meet the basic requirements of the CEPC detector design.

4.4 Full-silicon tracker detector

4.4.1 Introduction

The tracking system at CEPC are required to provide excellent tracking efficiency and precision over a wide range of momenta for charged particles from the interaction point as well as from the decay of secondary particles. The tracking system must be built with minimal material to preserve the momentum resolution and being covered hermetically down to the dip angle of $|\cos\theta| < 0.992$ from the beam pipe.

The full-silicon tracker offers a well known technology that provides excellent space point resolution and granularity to cope track separation in dense jets and hits from the high luminosity beam related background, which is an ideal tracker running at the Z-pole. The drawbacks include the relative high materia density within the tracking system, less redundancy, and limited dE/dx measurements. The purpose of this study is to demonstrate that the full-silicon tracking concept is a viable option for CEPC under the same detector boundary conditions used by the CEPC baseline detectors as summarized in the following:

- the solenoid B field is set to 3 Tesla,
- the tracking envelope consists of a cylinder with a radius of 1.83 m and a length of 4.6 m,
- the tracker covers down to 7.25 degree from the beam pipe,
- the Be beam pipe has a radius of 1.45 cm and 14 cm long.

There are two detailed design options for ILC detectors [50, 51], the large TPC+Silicon detector (ILD) and the compact full-silicon detector (SID), with very different detector configurations to achieve the same performances. Given the fact that the ILD and SID detectors costs very similar with very different sizes, we did not try to change the detector boundary conditions such as, the B field, the track volume given by the CEPC baseline detectors in order to achieve the optimal performances. However, within these boundary

conditions, we have optimized the layout with the number of silicon layers, single vs double sized, and support materials using a toy simulation described below.

4.4.2 Full silicon tracker layout

The CEPC baseline detector relies on a mixture of Time Projection Chamber (TPC) and silicon tracking system. However, the tracker could be converted using full silicon if the TPC is replaced with additional silicon stereo-strip layers (SIT) in the central region with disks of silicon stereo-strip detectors (FTD) on each side. In this design, the outer tracking system consists of a full-silicon tracker arranged as a set of six nested SIT layers in the central region with five FTD strip endcap disks on each side as shown in Fig. 4.27. Details for design of SIT and FTD detectors can be found in the discussion of CEPC baseline design [?] and we will use the same module design to build a full silicon detector as CEPC-FST. The pixel vertex detector (VTX) is kept the same as in CEPC v_4.

This new proposed tracking system provides at least 11 precisely measured points for all tracks down to a polar angle of about 15 degree and at least 7 measured points down to a polar angle of about 7.25 degree, as shown in Fig. 4.28. With three double pixel layers and forward disks covering a wide of polar angle, they are capable of providing excellent tracking on their own. The outer tracker adds additional track-finding constrains at large radii where hit density is low while improving the momentum measurement over a large level arm with excellent hit resolution in the transverse plane.

Alternatively, we start with the design of ILC-SID detector for CEPC by enlarging the outer silicon strip layers to fulfil the space up to a radius of 1.83 m and z at ± 2.3 m in order to achieve comparable momentum resolution using a lower solenoid B field of 3 Tesla as shown in Fig 4.27. The pixel detectors again are kept the same as in the ILC-SID design. We will label this option as CEPC-FST2, which provides an independent cross check on the tracking performance for a full-silicon tracker. The number of expected hits on the track from CEPC-FST2 is also shown in Fig. 4.28.

Table 4.7 summarizes the geometry parameters of the proposed outer strip silicon trackers for CEPC between two full silicon options.

4.4.3 Toy simulation

For each layout, we use a toy simulation (Idres) to calculate the expected tracking resolution as function of track momentum for a given incident angle θ , in which the effect of multiple scattering due to the material are taken into account correctly. Idres was developed by the ATLAS experiment [52]. The results are also cross checked using LDT program [53], which gives a consistent result.

The coverage of the full-silicon tracking system is shown in Fig. 4.28 as function of track pseudo-rapidity. At least 7 hits are measured for all tracks with a polar angle down to about 7.25 degree. The total radiation length for all-silicon tracking systems, including dead material such as readout, cables and supports, is about 5-7% for CEPC-FST and 7-10% for CEPC-FST2, respectively.

The expected momentum (p_T) and impact parameters (d_0 , and z_0) resolutions are compared as function of track p_T in GeV/c for tracks with $\theta = 85$ and 20 degree, respectively, as shown in Fig. 4.29. The z_0 resolution is better for CEPC-FST than for CEPC-FST2 due to extra stereo-strip layers while the p_T and d_0 resolutions are similar.

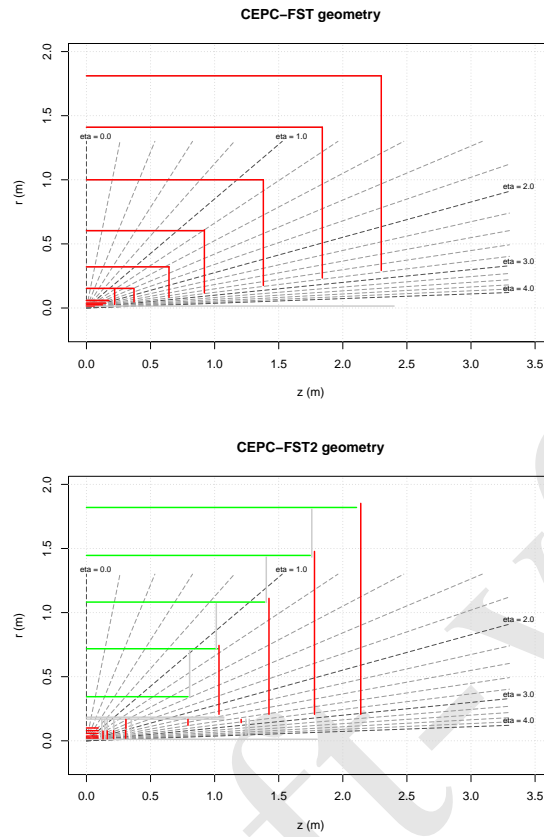

Figure 4.27: The R-Z view of the full silicon tracker proposed for CEPC-FST (left) and CEPC-FST2(right).

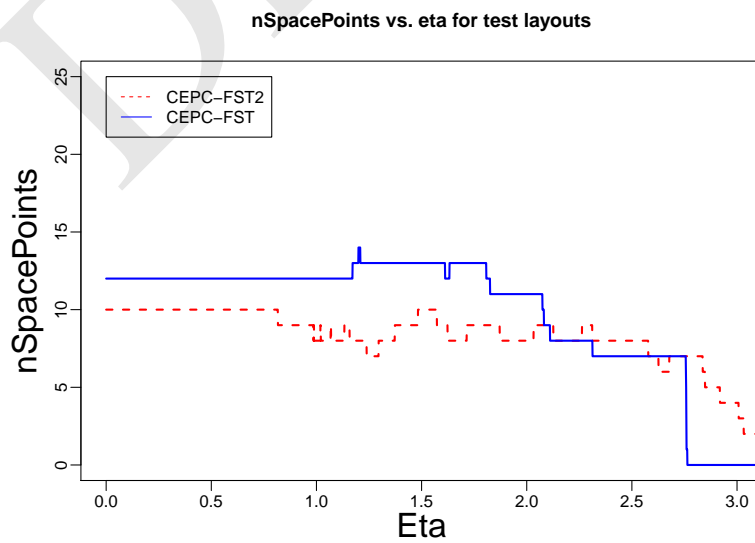

Figure 4.28: The number of expected hits are shown as function of track pesuro-rapidity.

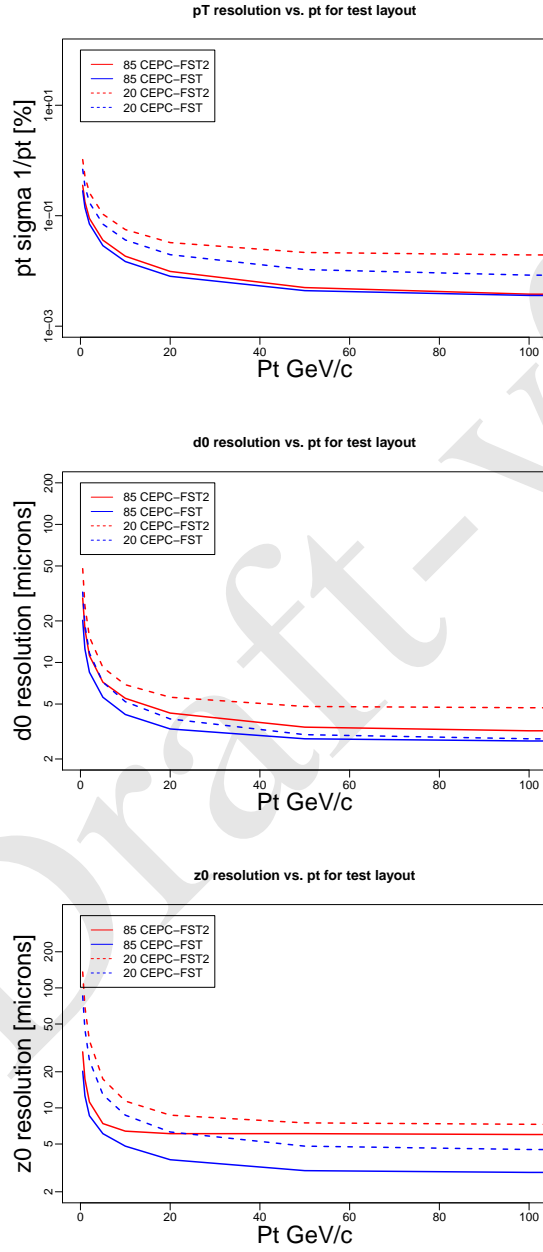

Figure 4.29: The expected p_T , d_0 , and z_0 resolutions from the toy simulation (Idres) are compared as function of track p_T in GeV/c for tracks with $\theta = 85$ and 20 degree, respectively.

Table 4.7: The proposed geometry parameters for the outer strip barrel layers and disks, where D and S stand for double and single-strip layer.

	CEPC-FST				CEPC-FST2			
Barrel	R (m)		$\pm z$ (m)	Type	R (m)		$\pm z$ (m)	Type
layer 0	0.153		0.368	D	0.344		0.793	S
layer 1	0.321		0.644	D	0.718		1.029	S
layer 2	0.603		0.920	D	1.082		1.391	S
layer 3	1.000		1.380	D	1.446		1.746	S

Disk 3	0.234	1.410	1.840	D	0.207	1.852	2.140	D
Disk 4	0.293	1.811	2.300	D				

4.4.4 Detector simulation and reconstruction

In order to optimize the full silicon tracker detector for CEPC, we generate several benchmark processes that include single muon events, $e^+e^- \rightarrow ZH \rightarrow \nu\nu\mu\mu$, and $e^+e^- \rightarrow ZH \rightarrow \nu\nu GG$ (two gluon jets). The events are then simulated and reconstructed using different detector geometries, which are then used for the tracking performance studies.

4.4.4.1 CEPC-FST detector

The implement of geometry for the CEPC-FST detector is based on a simulation tool Mokka[54]. The CEPC baseline detector is based on a version of database cepc_v4 [?], in which the tracker is composed of VXD, SIT, TPC, SET and FTD. In order to implement a full-silicon-tracker, the TPC and SET are considered to be replaced with a new silicon-based strip tracker based on the design of SIT layers and disks while keeping the rest of detectors same as in cepc_v4.

In order to improve the flexibility of design, a new package of SiTracker is implemented in Mokka which represents the silicon tracker by planar structure, which consists of a thin layer of silicon with $150 \mu m$ thickness and $50 \mu m$ pitch size. For VXD and SIT, they are composed by several layers, and each layer is composed by several ladders, and each ladder is divided to several sensors. The SIT layer consist of double silicon layers mounted back to back with a stereo-angle of 7 degree. For FTD, it is composed by several pixel disks FTD_PIXEL and several double-side strip disks FTD_STRIP that are composed by petals. The strip FTD disk has two sensitive silicon sub-layers on each side with a stereo-angle of 5 degree. The number of ladders/petals, the size and position of layers, and the

sub-structure of layers can be modified easily in input file as `globalModelParameter`. In future, a XML structure is considered as the method to input parameters.

The `lcio` format is used to output the simulated signals from the full-silicon-tracker, same as other sub-detector system [55]. The digitization and clustering are done in reconstruction process. In the default version, a smearing technology based on truth information is used as a simple digitization and clustering, which is used for this study. Recently, a new digitization for silicon-based detector has been developed. It first finds out the pixel which the hit is located, and uses the center of the pixel or strip as the new position for the hit. And then those hits in same pixel or neighboring will be merged into single hit.

A new conformal tracking algorithm has been adapted for the full silicon tracker, which is developed as the main track pattern recognition algorithm at CLIC [55] at FCC-ee. Through the conformal transform $u = \frac{x}{x^2+y^2}$ and $v = \frac{y}{x^2+y^2}$, where x and y are the positions of the track hits in the detector space, the positions of the track hits in the conformal space lie at a straight line for the track in a magnetic field. Therefore, track finding becomes straight line searching in the pattern recognition. Currently, a cellular automaton is used as pattern recognition for the straight line searching.

4.4.4.2 CEPC-FST2 detector

For CEPC-FST2, events were simulated and reconstructed using a software developed for the International Linear Collider (ILC) [50, 51], but re-worked for the HepSim project [56, 57]. The response of the CEPC-FST2 detector to physics events is simulated using the “Simulator for the Linear Collider” (SLIC) 5.0 software [58] interfaced with the GEANT4 10.3p1 program [59]. The track reconstruction was performed with the LCSIM 4.0 package [55] using the “seed tracker” algorithm as for the SiD detector simulation. Track candidates with at least six hits in the silicon pixel and microstrip layers were considered. Only tracks with a minimum transverse momentum (p_T) of 100 MeV were accepted. The track-fitting was performed with the following requirements; maximum distance of closest approach (DCA) is $|DCA| < 6$ mm, $|z_0| < 10$ mm, and fit $\chi^2 < 10$. The reconstruction includes particle-flow algorithms (PFA) which enable identification and reconstruction of individual particles. The PFA objects can be reconstructed using the software algorithms implemented in the PANDORA package [60, 61].

The geometry of CEPC-FST2 detector is implemented using the compact XML geometry description, which can load and built at runtime. The main changes over the ILC-SiD detector include the reduced B-field from 5 Tesla to 3 Tesla. The outer tracker is scaled up by a factor of about 1.44 to the radius of 1.83 m and z of ± 2.3 m. The silicon module sizes were appropriately scaled. The first inner layer of the barrel vertex detector was positioned at 15 mm, just outside of the beam pipe. The outer barrel layer of the silicon vertex detector was moved to 100.3 mm (vs 59 mm for the SiD detector), while other barrel layers are equally spaced. The forward disks, together with the support structures, were appropriately scaled in z by a factor 1.37.

As for the SiD detector, the barrel tracker consists of five layers of silicon sensors with 50 μm pitch. The forward tracker has four disks of silicon sensors. The silicon pixel detector had 20 μm pitch, consisting of five layers in the barrel and six disks in the forward region. The hadronic and electromagnetic calorimeters, as well as the muon detector, were optimized for CEPC physics as described in [62].

4.4.5 Tracking performance

After the detector simulation and reconstruction, the tracking performances are measured in terms of efficiencies, fake rates, momentum resolution, and the impact parameter resolutions using single muons or $e^+e^- \rightarrow ZH$ events. The tracking efficiency is defined as a fraction of stable charged particles that can be matched to well reconstructed tracks. The stable particles are defined as those charged particles with $p_T > 1$ GeV/c in the detector fiducial region ($9 < \theta < 170$ degree), originated from the interaction point, and lived long enough to reach the calorimeter. A well reconstructed track is defined as sharing more than 50% of its assigned silicon hits originating from a single particle (truth hits). We define a truth hit fraction as ratio of truth hits over total assigned hits of the track using silicon hits only. A poorly reconstructed track is defined to have the truth hit fraction less than 50%. The fake rate is defined as the fraction of poorly reconstructed tracks out of total reconstructed tracks, but this requires a realistic detector simulation, which we are not there yet. Since the CEPC baseline and the CEPC-FST detectors are sharing the common software and design, we will focus on their tracking performance comparisons to demonstrate that the full-silicon tracking concept is a viable option for CEPC.

4.4.5.1 Single muon particle

Figure 4.30 shows the tracking efficiency for single muons in CEPC-FST as function of p_T . The tracking efficiency is close to 100% at high p_T and slightly lower at small p_T . The trend is the same for CEPC baseline (v_4), which indicate both trackers are capable of finding tracks efficiently in the detector fiducial region.

The number of silicon hits found on the track are shown in Fig. 4.31 where the hit purity is reached close to 100% for both detectors.

Since the track resolution depends on the track angle θ , we divide the tracks in the barrel region with $40 < \theta < 140$ degree and in the endcap region with $7.25 < \theta < 40$ degree or $140 < \theta < 172.75$ degree. Figure 4.32 shows the track resolutions of p_T , d_0 , and z_0 as function of track p_T in the barrel and endcap region. The resolutions seem comparable to each other, but they seem slightly better for the low momentum tracks in the CEPC v_4 detector (TPC+Silicon) than CEPC-FST due to extra materia in the detector while they are compatible at the high p_T .

4.4.5.2 Di-muon mass resolution

Figure 4.33 shows the di-muon invariant mass distributions from $ZH \rightarrow \nu\nu\mu\mu$ decay between different detector configurations. The Higgs mass used in the simulation is 125 GeV/c². The di-mass from CEPC baseline detector seems shifted by 0.2 GeV from the input Higgs mass while the mass from CEPC-FST agrees with the expectation. The di-muon mass resolution from CEPC-FST has $\sigma = 0.21$ GeV/c² and seems 14% better than ones obtained from CEPC baseline detector.

4.4.5.3 Tracking inside the jets

In order to study the tracking performance inside the jets, we generated and simulated some Higgs decaying into two gluon jets (GG) in $ZH \rightarrow \nu\nu GG$ events. Figure 4.34 shows the tracking efficiency inside the jets as function of track momentum. The efficiency of finding tracks inside the jets is very similar between the CEPC baseline and the CEPC-FST detectors, which is close to 97%.

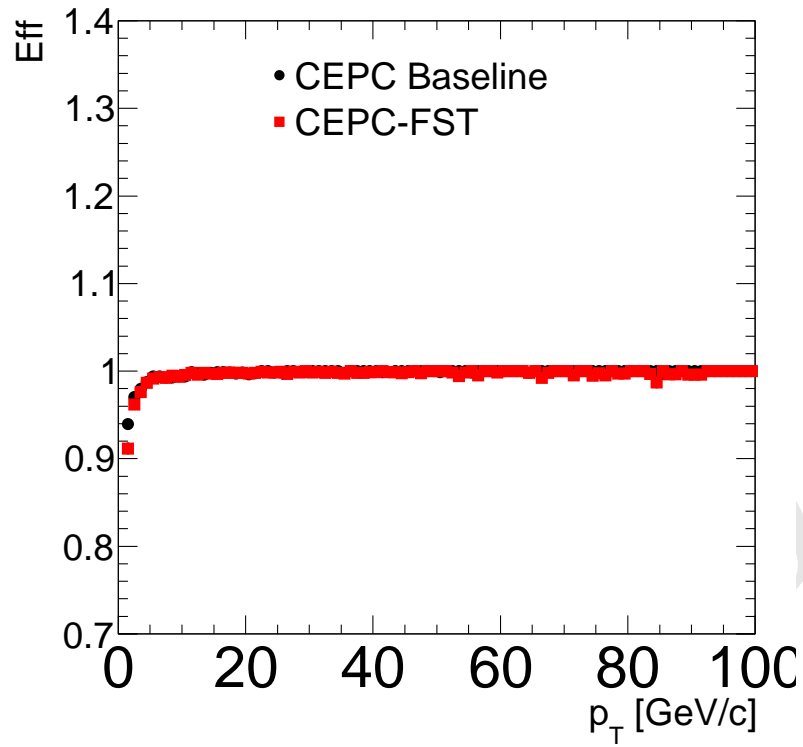

Figure 4.30: The tracking efficiencies are measured as function of p_T for single muons using CEPC baseline (v_4) and CEPC-FST detectors.

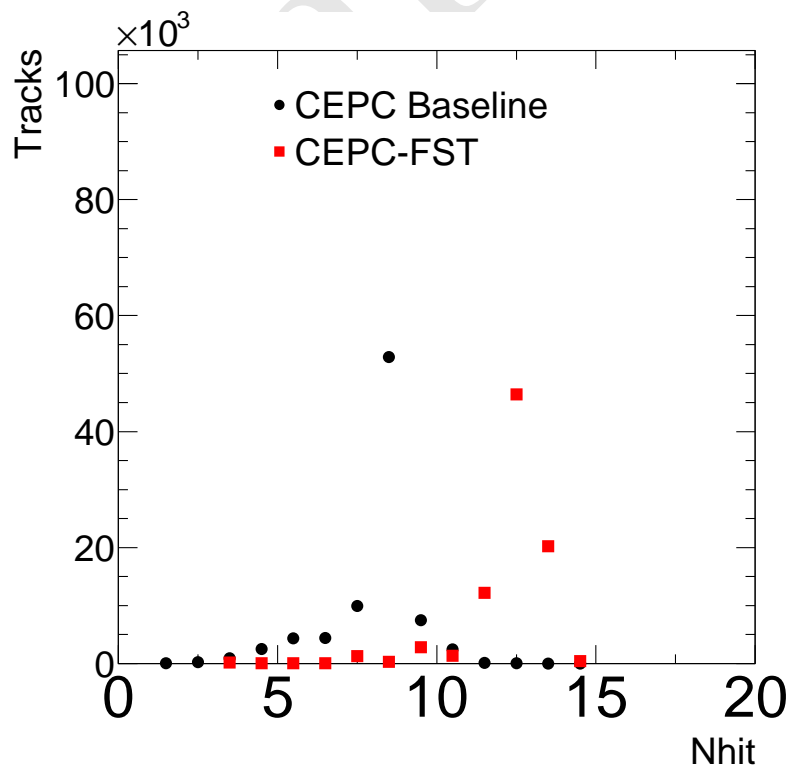

Figure 4.31: The distributions are shown for the number of silicon hits on the track.

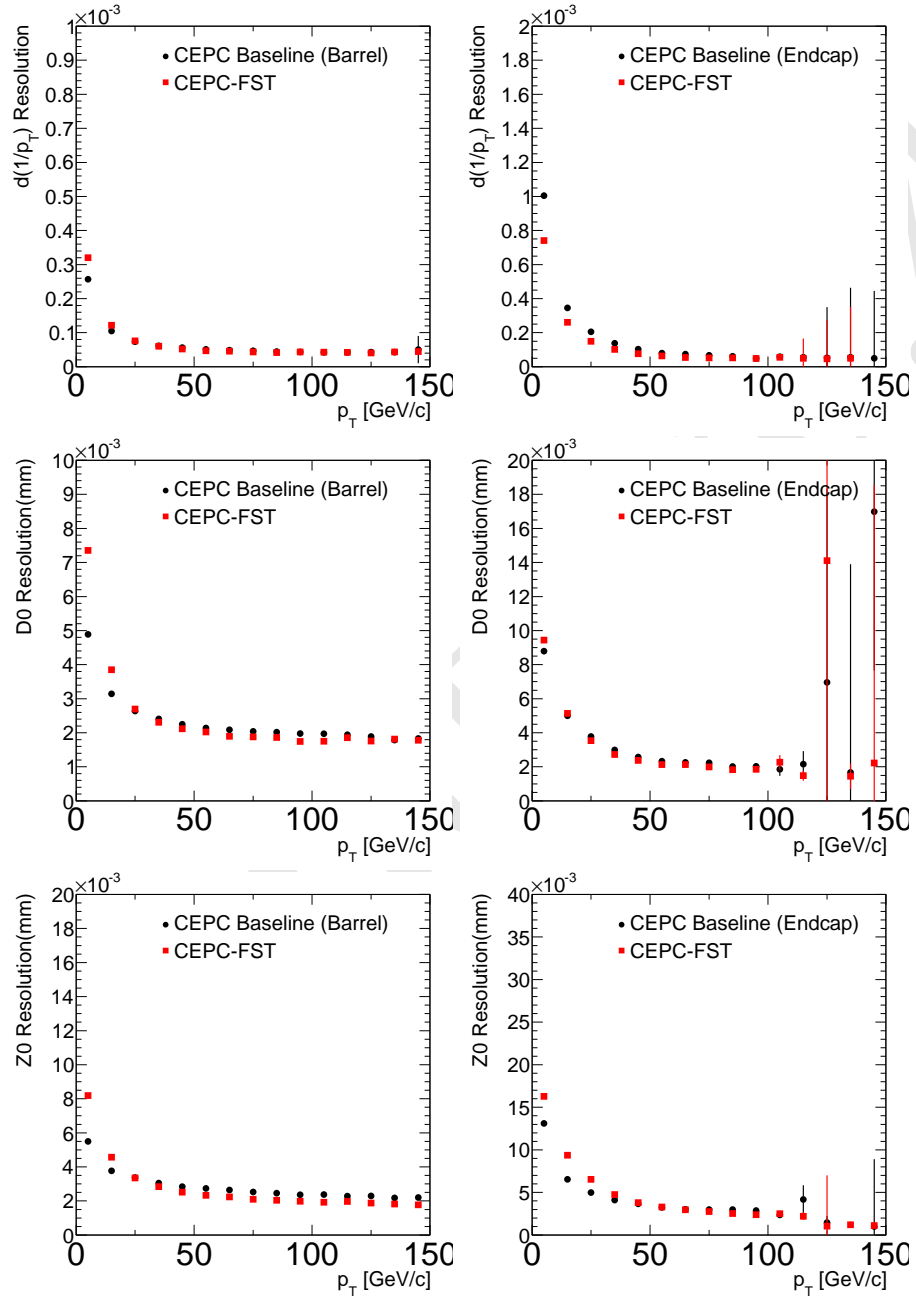

Figure 4.32: The tracking p_T , d0, and z0 resolutions are measured as function of p_T , ϕ , and θ using single muons, left in the barrel region and right in the endcap region. They are compared between CEPC v_4 and CEPC-FST detectors.

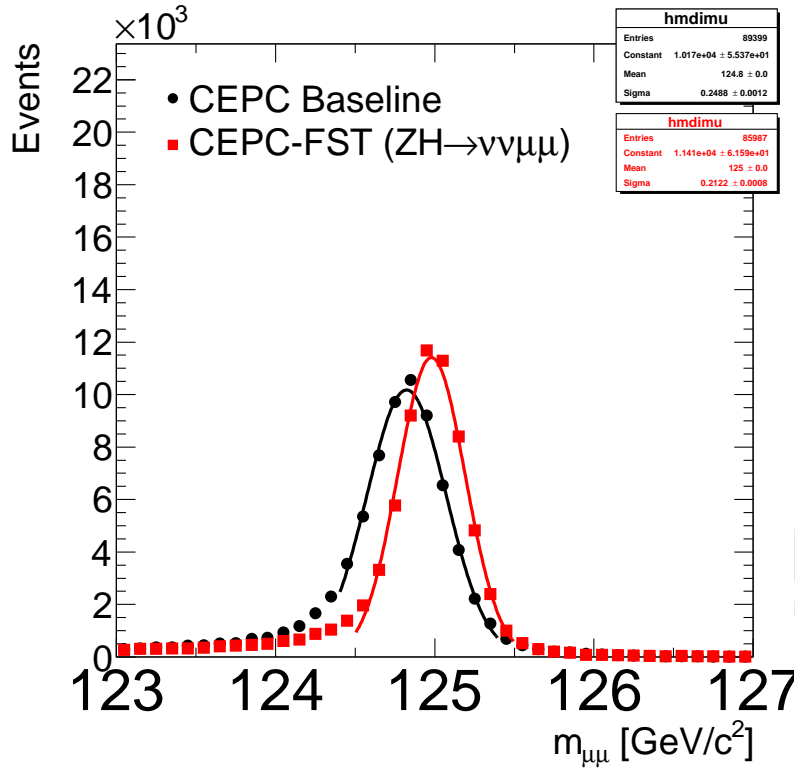

Figure 4.33: The di-muon mass distribution is compared from CEPC baseline and CEPC-FST detectors.

4.4.6 Conclusion

We present a preliminary study of full silicon tracker option as an alternative design for CEPC tracker. Two approaches are considered for the design: the first is to keep the silicon detectors (VXD, SIT, FTD) in the CEPC baseline detector and replacing TPC with additional silicon detectors, the second is to optimize the ILC-SID tracker to fulfil the CEPC tracking volume in order to achieve the excellent momentum resolution using 3 Tesla B field. The new detector geometry has been implemented in the simulation and the track reconstruction has also been adopted for the full silicon tracker. The initial study of the tracking performance looks promising. There are still many improvements needed in the simulation and reconstruction in order to explore the full potential of the full-silicon tracker.

4.5 Drift chamber tracker detector

4.5.1 Introduction

The drift chamber (DCH) is designed to provide good tracking, high precision momentum measurement and excellent particle identification by cluster counting.

Main peculiarity of this drift chamber is its high transparency, in terms of radiation lengths, obtained thanks to the novel approach adopted for the wiring and assembly procedures. The total amount of material in radial direction, towards the barrel calorimeter, is of the order of 1.6% X_0 , whereas, in the forward and backward directions, this is equiv-

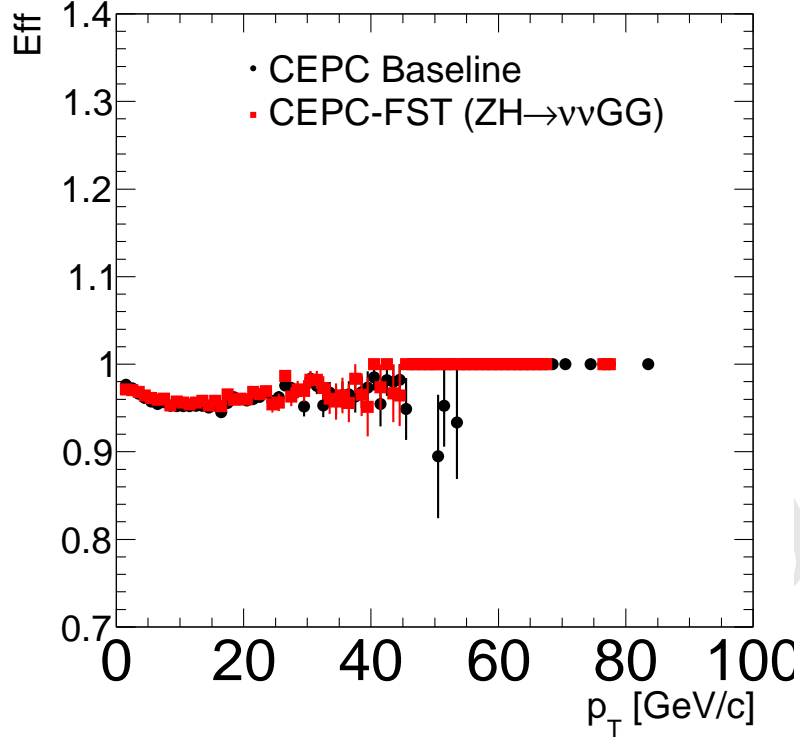

Figure 4.34: The tracking efficiencies for the stable particles inside the gluon jets as function of track p_T with CEPC v_4 and CEPSCSID.

alent to about 5.0% X_0 , including the endplates instrumented with front end electronics. The high transparency is particularly relevant for precision electroweak physics at the Z pole and for flavour physics, where the average charged particles momenta are in a range over which the multiple scattering contribution to the momentum measurement is significant.

Original ancestor of the DCH design is the drift chamber of the KLOE experiment[63], more recently culminated in the realisation of the MEG2[64] drift chamber.

4.5.2 Overview

The DCH is a unique volume, high granularity, all stereo, low mass cylindrical drift chamber, co-axial to the 2 T solenoid field. It extends from an inner radius $R_{in} = 0.35$ m to an outer radius $R_{out} = 2$ m, for a length $L = 4$ m and consists of 112 co-axial layers, at alternating sign stereo angles (in the range from 50 mrad to 250 mrad), arranged in 24 identical azimuthal sectors. The square cell size (5 field wires per sense wire) varies between 12.0 and 14.5 mm for a total of 56,448 drift cells. Thanks to the peculiar design of the wiring procedures, successfully applied to the recent construction of the MEG2 drift chamber, such a large number of wires poses no particular concern.

A system of tie-rods directs the wire tension stress to the outer endplate rim, where a cylindrical carbon fibre support structure bearing the total load is attached. Two thin carbon fibre domes, suitably shaped to minimise the stress on the inner cylinder and free to deform under the gas pressure without affecting the wire tension, enclose the gas volume.

The angular coverage, for infinite momentum tracks originated at the interaction point and efficiently reconstructed in space, extends down to approximately 13° .

In order to facilitate track finding, the sense wires are read out from both ends to allow for charge division and time propagation difference measurements.

The chamber is operated with a very light gas mixture, $90\%He - 10\%iC_4H_{10}$, corresponding to about 400 ns maximum drift time for the largest cell size. The number of ionisation clusters generated by a *m.i.p.* in this gas mixture is about 12.5 cm^{-1} , allowing for the exploitation of the cluster counting/timing techniques for improving both spatial resolution ($\sigma_x < 100\text{ }\mu\text{m}$) and particle identification ($\sigma(dN_{\text{cluster}}/dx)/(dN_{\text{cluster}}/dx) \approx 2\%$).

4.5.3 Expected performance

Figure 4.35 indicates a $100\text{ }\mu\text{m}$ drift distance resolution, averaged over all drift times, measured in a MEG2 drift chamber prototype[65] (7 mm cell size), with very similar electrostatic configuration and gas mixture. A better resolution is expected for DCH, because of the longer drift distances. Cluster timing technique may further improve it. Analytical calculations for the expected transverse momentum and angular resolutions are plotted in Figure 4.36.

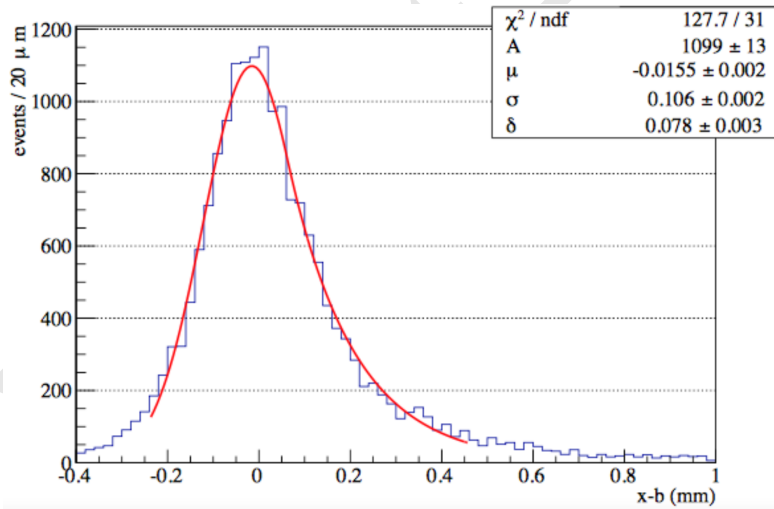

Figure 4.35: Measured drift distance residue distribution in the MEG2 drift chamber prototype under cosmic rays, indicating a resolution of less than $110\text{ }\mu\text{m}$, averaged over all drift times and in a wide range of track angles. $85\% He - 15\% iC_4H_{10}$ gas mixture.

Based on the assumption that one can, in principle, reach a relative resolution on the measurement of the number of primary ionisation clusters, N_{cl} , equal to $1/\sqrt{N_{cl}}$, the expected performance relative to particle separation in number of units of standard deviations is presented in Figure 4.37 as a function of the particle momentum. Solid curves refer to cluster counting technique applied to a 2 m track length with 80% cluster identification efficiency and negligible (a few percent) fake clusters contamination. Dashed curves refer to the best theoretical prediction attainable with the dE/dx technique for the same track length and same number of samples. For the whole range of momenta, particle separation with cluster counting outperforms dE/dx technique by more than a factor of

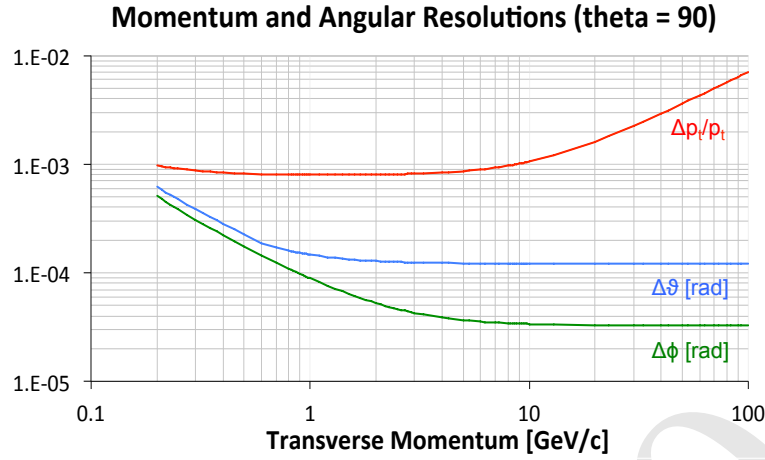

Figure 4.36: Momenta and angular resolutions as a function of the particle momentum for $\theta = 90^\circ$ (left) and of the polar angle for $p = 10 \text{ GeV}/c$ (right)

two, estimating an expected pion/kaon separation better than three standard deviations for all momenta below $850 \text{ MeV}/c$ and slightly above $1.0 \text{ GeV}/c$.

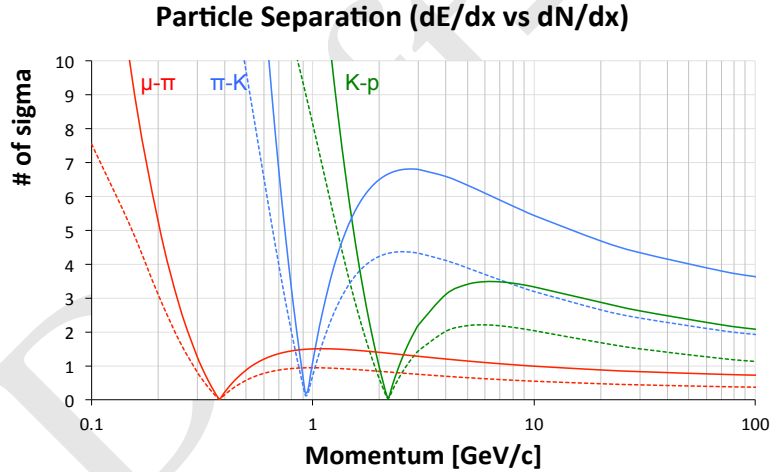

Figure 4.37: Particle type separation in units of standard deviations, with cluster counting (solid lines) and with dE/dx (broken lines) as a function of the particle momentum. A cluster counting efficiency of 80% and a dE/dx resolution of 4.2% have been assumed.

4.5.4 Tracking system simulation results

For the purpose of optimising the track reconstruction performance, a vertex detector (different from the baseline choice) made of seven cylindrical layers, inside the drift chamber inner radius, and of five forward disks, has been simulated together with a layer of silicon microstrip detectors surrounding the drift chamber both in the barrel and in the forward regions, followed by a pre-shower detector system within a homogeneous 2 T longitudinal magnetic field. Details of ionisation clustering for cluster counting/timing analysis have not been included in the simulations, limiting the drift chamber performance both in spatial resolution (a $100 \mu\text{m}$ gaussian smeared point resolution has been assumed) and in

particle separation (no dN_{cl}/dx analysis has been simulated). A simplified track finding algorithm at its preliminary stage of development has been used to feed the space points to the GenFit2 interface for the ultimate track fit. Figure 4.38 shows the momentum, angle and impact parameter resolutions obtained by the tracking system simulation. No optimisation has been tried yet. Momentum resolutions $\Delta p/p = 4 \times 10^{-3}$ at $p = 100 \text{ GeV}/c$, for $\theta = 65^\circ$, and angular resolutions $\leq 0.1 \text{ mrad}$ for $p \geq 10 \text{ GeV}/c$, are within reach. Lastly, a fit to the bottom right plot in Figure 4.38 gives a d_0 impact parameter resolution:

$$\sigma_{d_0} = a \oplus \frac{b}{p \sin^{3/2} \theta}$$

with $a = 3 \mu\text{m}$ and $b = 15 \mu\text{m} \cdot \text{GeV}/c$.

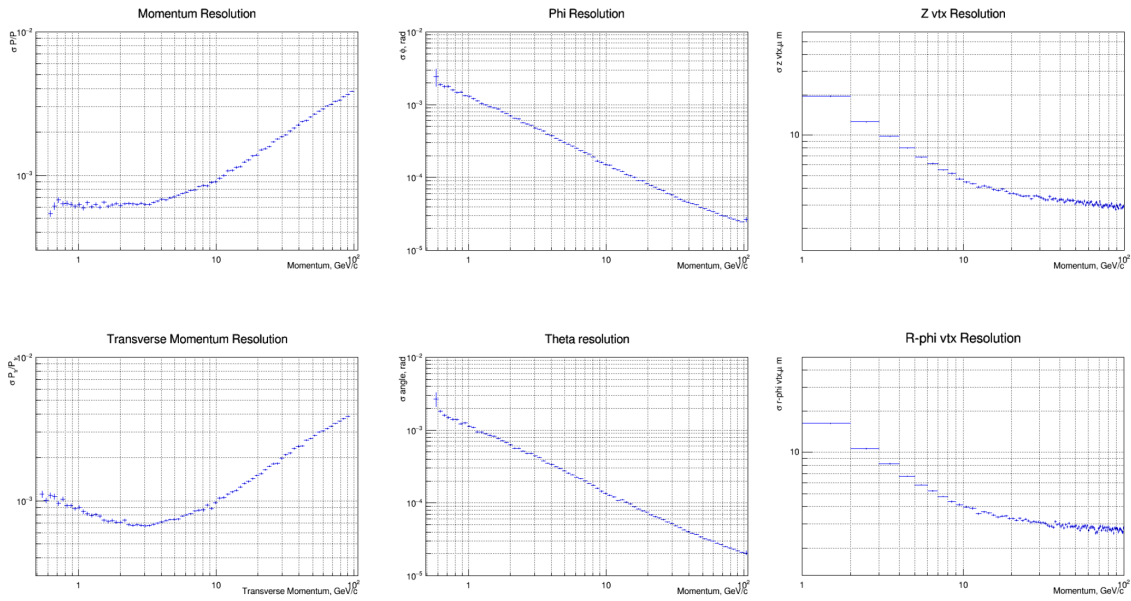

Figure 4.38: Momentum resolutions (top and bottom left), angle resolutions (top and bottom center) and impact parameter resolutions (top and bottom right) from simulation of isolated tracks.

4.5.5 Backgrounds in the tracking system

Of the main sources of backgrounds in the tracking system: incoherent pair production (IPC), synchrotron radiation and $\gamma\gamma$ to hadrons, IPC is the dominant one. However, only very few of the primary e^\pm particles will have a transverse momentum large enough to reach the inner radius of the drift chamber and the majority of the hits will be generated by secondary particles (mainly photons of energy below 1 MeV) produced by scattering off the material at low radii. Based on experience from the very similar MEG2 drift chamber, which has a smaller number of hits per track and a much more complicated event topology, occupancies of up to several percent will not affect tracking efficiency and single track momentum resolution. The level of occupancy here is expected to be even smaller with the use of the drift chamber timing measurement. As opposed to charged particles, indeed, that leave a string of ionisation in the drift cells they traverse, photons are characterised by a localised energy deposition. Signals from photons can therefore be

effectively suppressed at the data acquisition level by requiring that a threshold be reached by the number of ionisation clusters within a reasonable time window. In addition, charge strings with holes longer than the average cluster separation can be interpreted as due to separate signals, thus avoiding pilling up of any remaining photon induced background. With this effective suppression of photon induced signals, the background from IPC is expected to remain low and is unlikely to cause adverse issues for the track reconstruction.

4.5.6 Constraints on the readout system

With a drift chamber, all digitised hits generated at the occurrence of a trigger are usually transferred to data storage. The IDEA drift chamber transfers 2 B/ns from both ends of all wires hit, over a maximum drift time of 400 ns. With 20 tracks/event and 130 cells hit for each track, the size of a hadronic Z decay in the DCH is therefore about 4 MB, corresponding to a bandwidth of 40 GB/s at the Z pole (at a trigger rate of approximately 10 KHz). The contribution from $\gamma\gamma$ to hadrons amounts to 6 GB/s. As mentioned in the previous paragraph, the IPC background causes the read-out of additional 1400 wires on average for every trigger, which translates into a bandwidth of 25 GB/s. A similar bandwidth is taken by the noise induced by the low single electron detection threshold necessary for an efficient cluster counting. Altogether, the various contributions sum up to a data rate of about 0.1 TB/s. Reading out these data and sending them into an "event builder" would not be a challenge, but the data storage requires a large reduction. Such a reduction can be achieved by transferring, for each hit drift cell, the minimal information needed by the cluster timing/counting, i.e., the amplitude and the arrival time of each peak associated with each individual ionisation electron, each encoded in 1 Byte, instead of the full signal spectrum. The data generated by the drift chamber, subsequently digitised by an ADC, can be analysed in real time by a fast read-out algorithm implemented in a FPGA[66]. This algorithm identifies, in the digitised signal, the peaks corresponding to the different ionisation electrons, stores the amplitude and the time for each peak in an internal memory, filters out spurious and isolated hits and sends these reduced data to the acquisition system at the occurrence of a trigger. Each hit cell integrates the signal of up to 30 ionisation electrons, which can thus be encoded within 60 B per wire end instead of the aforementioned 800 B. Because the noise and background hits are filtered out by the FPGA algorithm, the data rate induced by Z hadronic decays is reduced to 3 GB/s, for a total bandwidth of about 3.6 GB/s, roughly a factor 30 reduction.

CHAPTER 5

CALORIMETRY

5.1 Introduction to calorimeters

A calorimetry system is employed in the CEPC detector for precise energy measurements of electrons, photons, taus and hadronic jets. To fully exploit the potential of the CEPC for Higgs and electroweak physics, the energy resolution of the CEPC calorimetry system for hadronic jets needs to be pushed quite beyond today's limits. This is a jet energy resolution of 3%-4%, or $30\%/\sqrt{E}$, required at energies below about 100 GeV. This resolution is about a factor of two better than that provided by the LEP detectors and the currently operating calorimeters at the LHC, and would significantly improve the separation of the W and Z bosons in their hadronic decays, as shown in Figure 5.1. Two different technology approaches are pursued for the CEPC calorimetry system, the first one aiming to measure individual particles in a jet using a calorimetry system with very high granularity based on the particle flow concept, while the second aiming at a homogeneous and integrated solution based on the dual-readout concept. Both approaches will be described in this chapter, while the first approach is the baseline for the design of the CEPC calorimetry system in that it is integrated in the full CEPC detector simulation.

The particle flow algorithm (PFA [1]) is a very promising approach to achieve the unprecedented jet energy resolution of 3%-4%. The basic idea of the PFA is to make use of the optimal sub-detector in a detector system to determine the energy/momentum of each particle in a jet. An essential prerequisite for realization of this idea is to distinguish among energy deposits of individual particles from a jet in a calorimetry system. And high three-dimension granularity is required for the calorimetry system to achieve this. So PFA calorimeters all feature extremely fine three-dimension granularity which al-

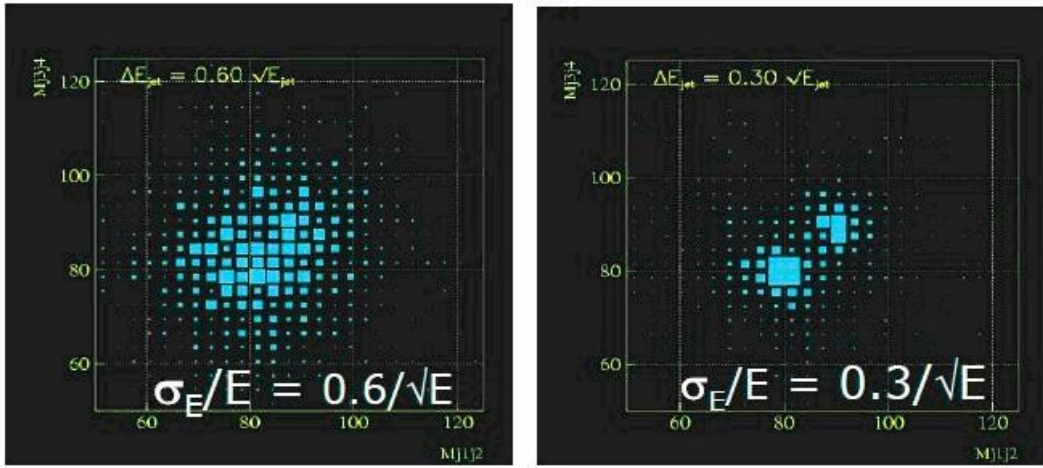

Figure 5.1: Separation of W and Z bosons in their hadronic decays with different jet energy resolutions.

allows reconstruction and identification of every single particle showers in a jet. It is for this feature PFA calorimeters are usually also called imaging calorimeters. A PFA calorimetry system generally consists of an electromagnetic calorimeter (ECAL), optimized for measurements of photons and electrons, and a hadronic calorimeter (HCAL) to measure hadronic showers.

In a typical jet, 65% of its energy is carried by charged particles, 25% by photons and 10% by neutral hadrons. The charged particles in a jet can be precisely measured with a tracking system and their tracks can be matched to their energy deposits in a PFA calorimetry system. Energy deposits in the PFA calorimetry system without matched tracks are considered to originate from the neutral particles of photons and neutral hadrons in the jet. Among these neutral particles, photons are measured using the ECAL with good energy resolution, while only the neutral hadrons are primarily measured using the HCAL with a limited energy resolution. So in the PFA, the jet energy is determined by combining the best measurement in a detector system of each single particle in the jet: the track momenta of charged particles measured using the tracking system, the energies of photons measured using the ECAL and the energies of neutral hadrons measured primarily using the HCAL.

Enormous studies have been carried out within the CALICE collaboration [2] to develop compact PFA calorimeters. Various detector technology options have been explored to address challenges from stringent performance requirements as shown in Figure 5.2. Prototypes with extremely high granularity using several technological options have been developed and exposed to particle beams, which have demonstrated the in-depth understanding of the PFA calorimetry performance.

An alternative approach for a combined, high-performance, electromagnetic and hadronic calorimeter aims at reaching even better (standalone) resolutions by exploiting the dual-readout (DR) technique. Indeed the main limiting factor to the energy resolution in hadron calorimetry arises from the fluctuations of the electromagnetic component (f_{em}) that each hadronic shower develops as consequence of π^0 and η production. Since typically the detector response to the hadronic and em components is very different ($h/e \neq 1$), the reconstructed signal heavily depends on the actual value of f_{em} . By using two independent

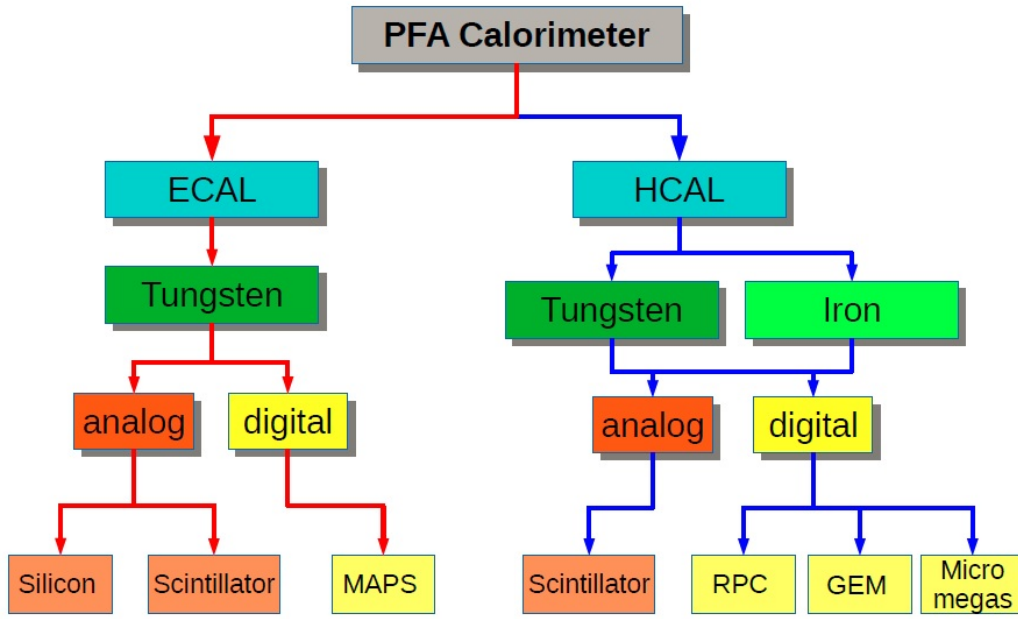

Figure 5.2: PFA: Imaging calorimeters being developed by the CALICE collaboration since 2000.

processes (namely scintillation and Čerenkov light production) that have a very different sensitivity to the hadronic and em components, it is possible to reconstruct f_{em} , event by event, and eliminate the effects of its fluctuations.

Among the possible DR implementations, a fibre-sampling DR calorimeter, based on either copper or lead as absorber material, looks the most suitable to provide the required performance in a cost-effective way. Preliminary results of Geant4 simulations point to possible resolutions better than 15% and around 30% – 40% (over \sqrt{E}), for electromagnetic and hadronic showers, respectively (see section 5.5.6).

Moreover, if the fibres are readout with SiPM, the high detector granularity and the possibility of longitudinal segmentation will make this solution easily compatible with Particle Flow Algorithms.

5.2 General design considerations for the PFA Calorimetry system

The CEPC PFA calorimetry system is longitudinally composed of two separate sampling calorimeters: ECAL and HCAL, both of which are installed inside the solenoid coil of the CEPC detector system to minimize the inactive material in front of the calorimetry system and to reliably associate tracks to energy deposits. Following the geometry of the CEPC detector, each of two calorimeters is organised into one cylindrical barrel and two disk-like end-cap sections.

The ECAL is considered to have analog readout, consisting of sensitive layers of either silicon pads or scintillator tiles interleaved with tungsten absorber plates. As for the HCAL, steel plates are adopted as absorber, and both digital and analog readout is considered. The digital HCAL (DHCAL) uses either glass Resistive Plate Chambers (gRPC) or Thick GEM detectors (THGEM) as active medium, while the analog HCAL (AHCAL) uses scintillator tiles coupled with SiPM.

The calorimeters for these options are all highly segmented both transversely and longitudinally, which is driven by the requirement from the particle flow algorithm of excellent particle shower separation capability. The baseline technology options for the CEPC PFA ECAL and HCAL that have been integrated into the full CEPC detector simulation are silicon-tungsten and steel-gRPC, respectively. In the baseline design of the calorimeters, the ECAL is segmented into 30 longitudinal layers with a total depth of $24 X_0$, and the silicon plate in each layer is divided into square cells each of $5 \times 5 \text{ mm}^2$. The HCAL consists of 40 longitudinal layers each containing 2 cm thick steel with a thin layer of gRPCs read out in a cell size of $10 \times 10 \text{ mm}^2$. Further optimization on cell sizes for both the ECAL and HCAL based on benchmark physics processes is underway.

5.3 Electromagnetic Calorimeter for Particle Flow Approach

The particle flow paradigm has tremendous impact on the design of the ECAL. With excellent capability of pattern recognition, The ECAL is expected to identify photons from close-by showers, reconstruct detailed properties of a shower (i.e. shower shape, starting point and energy distribution), and distinguish electromagnetic showers from hadronic ones. Thus shower imaging capability of the calorimeter is more important than its intrinsic energy resolution, although the latter is still important to the particle flow performance for electrons, photons and jets. Due to the fact that about half of hadronic showers start inside the ECAL, excellent three dimensional granularity is of primary importance to the ECAL. In order to have the power of separating close-by showers in the calorimeter, absorber material with small Moliere radius is required for the ECAL. And a large ratio of the interaction length over the radiation length of the absorber material is advantageous to separation between electromagnetic and hadronic showers because a short radiation length makes an electromagnetic shower start early in the ECAL, while a long interaction length reduces the fraction of a hadronic shower in the ECAL. A short radiation length also makes a compact ECAL, which is highly desirable from the cost saving point of view.

In short, requirements for the ECAL on high granularity, compactness and shower separation lead to the choice of a sampling calorimeter with tungsten (the radiation length $X_0 = 3.5 \text{ mm}$, the Molière Radius=9 mm and the interaction length $\lambda_I = 99 \text{ mm}$) as absorber material. This ensures a compact ECAL with a depth of around $24 X_0$ within 20 cm.

Two options for active material are considered for the ECAL: silicon and scintillator. The silicon option is taken as the baseline, while the scintillator option is also being investigated as alternative. Both options are presented in this section.

The baseline design of the ECAL consists in a layout of 30 longitudinal layers of silicon sensors sandwiched between tungsten plates with a sensor size of $5 \times 5 \text{ mm}^2$ and a total depth of $24 X_0$.

5.3.1 Silicon-Tungsten Sandwich Electromagnetic Calorimeter

5.3.1.1 Silicon sensors

Among several sensor techniques, silicon PIN diodes with high resistivity offer several unique intrinsic advantages as follows.

- **Stability:** under a reasonable bias voltage, a completely depleted silicon PIN diode have a gain of one, and a signal response to a Minimum Ionizing Particle (MIP) mostly

defined by the sensor thickness, with a relatively low dependence on the operating environment including temperature, humidity, etc.

- **Uniformity:** the control of the sensor thickness within large production batches (typically to less than a percent) ensures uniform responses within a wafer and between different wafers. The non-sensitive area between wafers has recently been reduced by the use of laser cutting, thinned guard-ring design [3], and would benefit from the use of larger ingot size (8" becoming the standard).
- **Flexibility:** the dimension and geometry of the cells can be flexibly defined. The readout pads on the PCB need to be compatible.
- **High signal-to-noise (S/N) ratio:** for a MIP, the most probable number of electron-hole pairs generated in $1\mu\text{m}$ thick silicon is around 76 (while the average number is 108), which yields an excellent S/N ratio of silicon sensors. Thus MIP tracks can be easily tracked in the calorimeter, which is critical to the good performance of the ECAL.

Currently the only drawback of the silicon sensors is the price, which is expected to be around $2 - 3\$/\text{cm}^2$.

By associating of silicon sensors with tungsten plates and carbon fiber structures, the SiW-ECAL offers an excellent option for the PFA optimized calorimetry.

5.3.1.2 Geometry and mechanical design

A key requirement for the calorimeter system is to ensure the best possible hermeticity. Three regions need to be taken account, including the boundaries of mechanical modules, the overlap between the barrel and endcap parts, and the small angle region near the luminosity monitor (or other forward detectors). A design with large ECAL modules is preferred to minimize the number and effect of cracks in the barrel part. The inter-module boundaries should not point back to the interaction point (IP). As shown in Figure ??, an octagonal shape is used to approximate the cylindrical symmetry and the modules are such designed that that the cracks are at a very large angle with respect to the radial direction. One eighth of the barrel ECAL is named a stave. Each stave will be fastened to the HCAL front face with a precise system of rails. Some space will be left between the ECAL and HCAL to accommodate services including cooling, power and signal cabling. Along the beam direction, a stave is divided into five modules. The two ECAL endcap parts will be fastened to the front face of HCAL endcap parts using a similar rail system.

ECAL longitudinal arrangement In the the ECAL baseline design featuring 30 layers in the longitudinal direction, split into 2 sections. The first section contains 12 radiation lengths and are filled with 20 layers of $0.6X_0$ (or 2.1 mm) thick tungsten plates. Each sensitive layer is equipped with $525\mu\text{m}$ thick silicon sensors. It is followed by the second section with another 11 radiation lengths made from 9 layers of $1.2X_0$ thick (4.2 mm) tungsten plates. The ECAL starts with an active layer. The choice of the silicon layer granularity is fixed at $5 \times 5\text{mm}^2$. The first and second sections both hold a base plate (carbon-fiber) of 20 mm thick, and are 223 mm, 191 mm thick in total respectively.

ECAL dimensions The ECAL barrel part consists of 8 staves, each with 5 trapezoidal modules. A barrel module contains 5 columns (a column is also named alveolus). The numbers of modules and alveoli are chosen to be odd in order to avoid any pointing-like

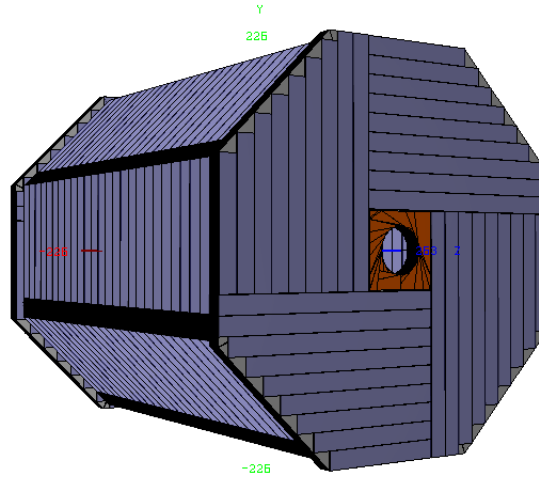

Figure 5.3: Schematic of the CEPC ECAL layout.

dead region at the azimuthal plane perpendicular to the beam direction at the IP. The alveolus size is fixed to 186 mm by mechanical limits and by cost optimization considerations, in order to contain exactly two 6-inch wafers or one and a half 8-inch wafers. Integrating the alveolus size, walls of modules and contingencies, the barrel length adds up to 4700 mm. (4900mm is used in the CEPC simulation). A gap of typically 70mm (100mm in the CEPC simulation) is left between the barrel sides and end-cap front parts. But the precise dimension will depend on the amount of services for the ECAL, the HCAL and the tracker system (including power and DAQ cabling, cooling pipes, patch panels, etc.).

The end-caps are made of quadrants of 2 modules of 4 and 3 alveoli columns. Their inner radius is fixed by the ECAL ring at 400mm. With 7 alveoli columns, the end-cap outer radius is 1755mm. An overshoot of 32mm is left between the outer radius of the barrel and of the end-caps, in order to contain the EM shower impinging the region of overlap. see figure 5.4. This fixes the inner radius size of the ECAL barrel at 1498mm or 1530mm. For such a geometry, summing the barrel (200) and end-caps (56), 256 alveoli columns are needed. For 22 (resp. 30) layers, and this yields 5632 (7680) alveoli, and as many detector slabs.

ECAL slab Several slabs are inserted into each column of the ECAL modules. Each slab consists of two symmetric sensitive layers and one tungsten plate. Each sensitive layer contains a layer of silicon sensors glued on a PCB, equipped with readout ASICs, a high voltage distribution by a Capton foil and copper layers for passive cooling. The components are attached on both sides of an H-shaped carbon fibre cradle, with a tungsten core, and shielded by an aluminum cover. To insure scalability and industrial production, the design has been made as modular as possible: each basic unit is an ASU (Active Sensor Unit), which currently has a $18 \times 18 \text{ mm}^2$ PCB glued with 4 pieces of $90 \times 90 \text{ mm}^2$ silicon wafers. Each ASU will handle 256 silicon pads with 4 ASIC chips, for the cell size of $11.25 \times 11.25 \text{ mm}^2$.

The ASUs are chained together for the clock and configuration distributions and data collection. For a radius of 1498mm the longest (shortest) barrel slabs measure 1146mm (955mm).

5.3.1.3 SiW-ECAL electronics

One of the most critical element of the CEPC calorimeters is the readout electronics which is defined by the dynamic range, the effective digitisation, mode of trigger, the rate of working and power consumption per channel.

Dynamic range: A MIP going through a $725\ \mu\text{m}$ silicon diode will produce around 60000 electron-pairs holes (or a charge of 9.6 fC) as the most probable value (MPV). To record MIPs with an efficiency higher than 95 %, this determines the lower limit of the dynamic range to a 1/3 of the MPV. The higher limit is given by the number of MIP equivalents at the core of the high-energy EM showers, which can reach up to 10000 MIPs (or 96pC) within a $11 \times 11\ \text{mm}^2$ cell.

Timing: Time measurements of energy depositions in the calorimeters can be useful to Particle Flow algorithms to help disambiguate particle contributions. For the CEPC as a lepton collider, normally with a single primary vertex, precision timing of individual cells - or group of cells - could still be useful to reduce the confusion in the calorimeters and improve the energy resolution, which however needs further studies to quantitatively explore this potential. A SiW-ECAL ASIC with the most recent version (SKIROC2A) has been tests on a test board and reached a measure of timing resolution close to 1.1 ns [4].

Power consumption: The running conditions a circular collider exclude any pulsed operation as is planned for the linear colliders. As a point of reference, the current power consumption for the SKIROC2 chip is around 5 mW per channel in the continuous operating mode.

Occupancy: The occupancy of the calorimeters is expected to be very low. This offers room for an ultra-low power electronics design when there is no signal.

5.3.1.4 SiW-ECAL power consumption and cooling

To the first order, the amount of the power dissipation scales up with the number of electronics channels. One critical issue for the calorimeters is on the cooling scheme. As for now there are two options. The CEPC ECAL is at the boundary of both options, with a limit for the purely passive option of the order of $2 \times 2\ \text{cm}^2$ cells for a increase of temperature limited to $\Delta T \sim 10\ ^\circ\text{C}$ at the far end of the slab.

- **Passive cooling:** this option requires a reduced number of channels in order to use only passive cooling at the hear of the detector. As an example, a $400\ \mu\text{m}$ thick copper sheet will drain the heat to the end of an ECAL slab, where it is then removed by an active cooling system installed near boundaries between barrel and endcap parts. A leak-less water cooling system can be such an option to extract the heat at the end of each slab from the copper. Details of implementation can be found in [5?]. Full simulation studies based on PFA should be performed to provide quantitative hints on the reduced granularity and the corresponding calorimeter performance.
- **Active cooling:** this options can keep the high granularity design as the baseline, but need to instrument a cooling system in the whole calorimeter system. A two-phase CO_2 cooling system is a promising option, which can be embedded in the absorber plates. There are already some simulation studies on the similar system adapted to the SiW-ECAL [6], where 3mm thick copper plates, equipped with 1.6 mm inner diameter pipes for CO_2 circulation, with the ASICs glued on both side of the slab. Assuming a fully transversally isolated system, with ASICs a sole heat source at equilibrium dissipating 0.64 W (10 mW per channel times 64 channels), and a fixed working point

of 20 °C for CO₂ (i.e assuming perfect heat absorption), a doubled-sided module of 252 × 252 mm² holding 32 chips cooled by 2 × 2 pipes was simulated. Preliminary simulations in "ideal conditions" show a difference of $\Delta T \sim 2$ °C mostly centered on ASIC's (0.3 °C in the exchanger itself only).

5.3.1.5 SiW-ECAL R&D status

The performances of a SiW-ECAL have been explored using the "physical prototype" developed within the CALICE collaboration, with extensive beam tests during the years 2005- 2011 [7–9]. Some ASUs have been operated in beam test campaigns: first at CERN in 2015, where 3 ASUs were mounted on test boards which behaved as expected [10]; a signal to noise ratio (SNR) (defined as the Most Probable Value of a Landau fit on data, divided by the Gaussian width of the noise) reached typical values of 15-18, with a very limited number of masked channels.

In a recent beam test at DESY with 1-5 GeV electrons, "short slabs" (featuring all the elements as required but limited to a single ASU on a single side) could reach a SNR of around 20 on average [11].

The collected data is still under analysis, but they are expected to be similar to the SiW-ECAL physical prototype. The construction of a "long slab" is being actively pursued, and should be completed toward the end of year 2019; the R&D involves all the power, cooling and front-end electronics issues. The results and design will have to be optimized for a circular collider, where the power-pulsing operation is not allowed.

5.3.2 Scintillator-Tungsten Sandwich Electromagnetic Calorimeter

5.3.2.1 Introduction

Alternatively, a sampling calorimeter with scintillator-tungsten structure is proposed. It can be built in a compact and cost effective way. The structure of the ScW ECAL is similar to the SiW ECAL. The major geometry parameters of the ScW ECAL are also studied and optimized, with the similar results of the SiW ECAL. The active layers of the ScW ECAL are consisting of 5×45mm² scintillator strips. The scintillator strips in adjacent layers are perpendicular to each other to achieve a 5×5mm² effective transverse readout cell size. Each strip is covered by a reflector film to increase collection efficiency and improve uniformity of the scintillation light. Photons from each scintillator strip are read out by a very compact photo-sensor, SiPM, attached at the end of the strip. The SiPM and highly integrated readout electronics make the dead area in the ScW ECAL almost negligible.

Plastic scintillator is a robust material which has been used in many high energy physics experiments. Production of the scintillator strips can be performed at low cost by the extrusion method. Moreover, the number of readout channels can also be significantly reduced due to the strip structure. So the total construction cost of the ScW ECAL is lower than the SiW ECAL. Some key issues which might affect the performance of the ScW ECAL were studied and optimized.

5.3.2.2 SiPM dynamic range study

Because each pixel on a SiPM can only detect one photon at once and a few nanoseconds are needed before recovery, the SiPM is not a linear photon detection device, especially

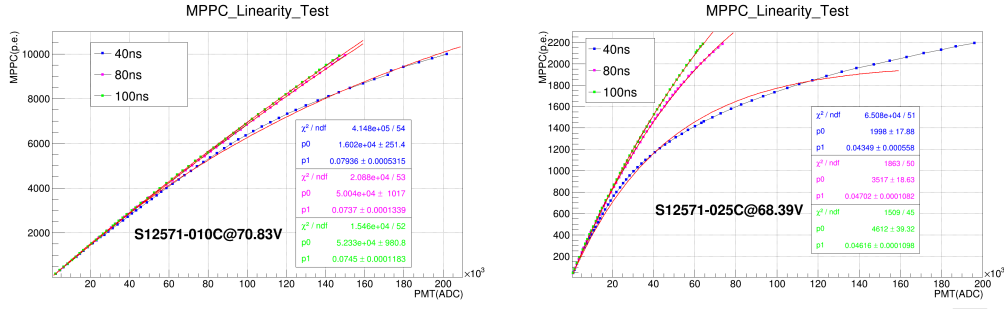

Figure 5.4: The response curve of 10000-pixel(left) and 1600-pixel(right) SiPMs for different illuminating durations.

in the case of high intensity light input. The application of the SiPM in the CEPC ScW ECAL is a challenge to its dynamic range, which need to be studied.

For a short time light pulse, the response of the SiPM can be theoretically calculated as

$$N_{fired} = N_{pixel}(1 - e^{-N_{pe}/N_{pixel}}) \quad (5.1)$$

However, for the ScW ECAL, the width of the light pulse should not be ignored, and some pixels of the SiPM can detect more than one photon in an event. The response of the SiPM should be modified as

$$N_{fired} = N_{eff}(1 - e^{-N_{pe}/N_{eff}}) \quad (5.2)$$

The N_{eff} stands for the effective number of pixels on a SiPM, which is relative to the width of the input light pulse. Response curve of 10000 pixel ($10\mu\text{m}$ pitch size) and 1600 pixel ($25\mu\text{m}$ pitch size) SiPM with different duration light have been tested. As shown in Figure 5.4, the output linearity of the device is improved by the increase in the incident light width.

5.3.2.3 Scintillator strip test

Because the SiPM is coupled at one end of the scintillator strip, the light output will be non-homogeneous along the length of the scintillator, which will affect the performance of the ScW ECAL. By moving a Sr^{90} source along the length of the scintillator, we test the light pulses height read out by the SiPM to study the non-uniformity of the scintillator detector. Figure 5.5(left) is a typical test result of a scintillator module whose light output non-uniformity is 23%. The uniformity can be improved by optimizing the reflection material or the coupling methods of the SiPM to the scintillator strip. Figure 5.5(right) shows a result of a scintillator module with the SiPM embedded into the scintillator strip, and Figure 5.6 is the light output of another scintillator module with different reflector. Scintillators with ESR reflector can give much more light output. We have also test the light output of the scintillator coupled with the SiPM with different pitch size. Two kinds of SiPM have same sensitive area ($1\text{mm} \times 1\text{mm}$), but have pitch size of $25\mu\text{m}$ and $10\mu\text{m}$ respectively. The light output of the scintillator with $25\mu\text{m}$ pitch SiPM is only about 1/3 of the scintillator with $10\mu\text{m}$ pitch SiPM, shown in Figure 5.7.

5.3.2.4 SiPM readout electronics

The readout electronics of the ECAL has to provide high dynamic range of energy, while showers of particle may deposit $1 \sim 800$ MIPs energy in single cell for 100GeV photon.

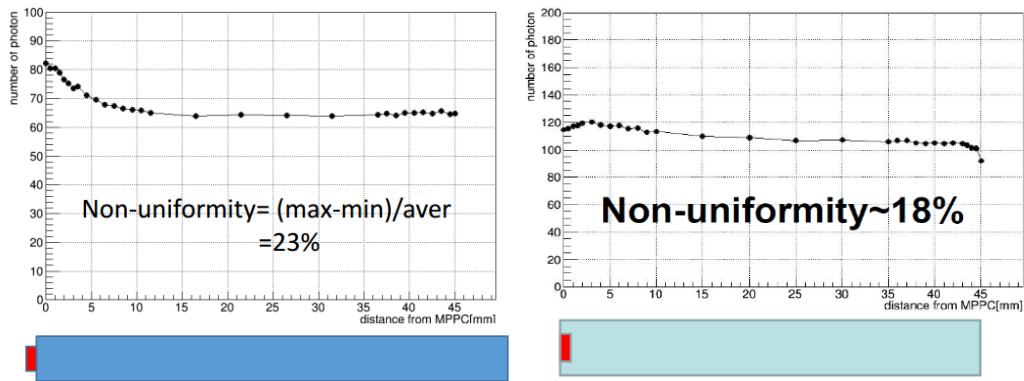

Figure 5.5: Uniformity of scintillator strips with SiPM coupled on side surface (left) or embedded into one side (right).

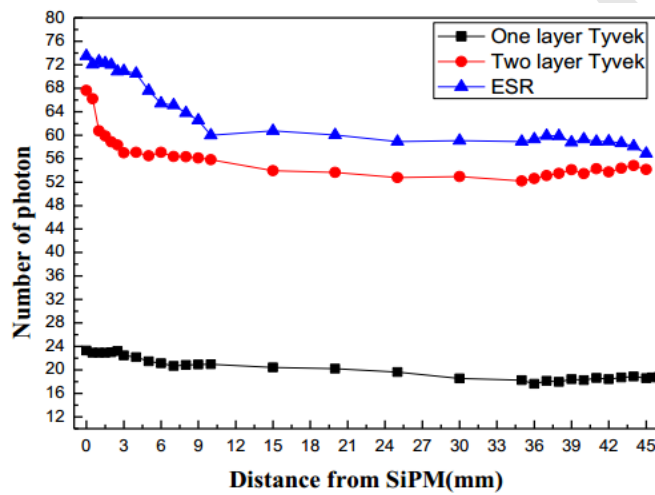

Figure 5.6: light output of scintillators with different reflectors.

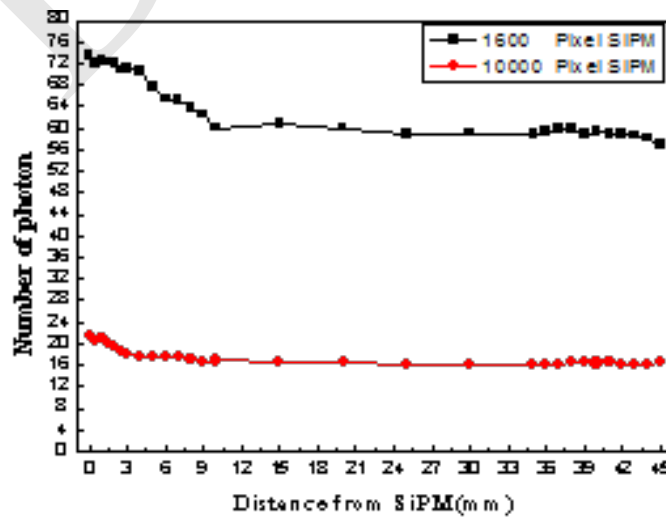

Figure 5.7: light output of scintillators with different SiPMs.

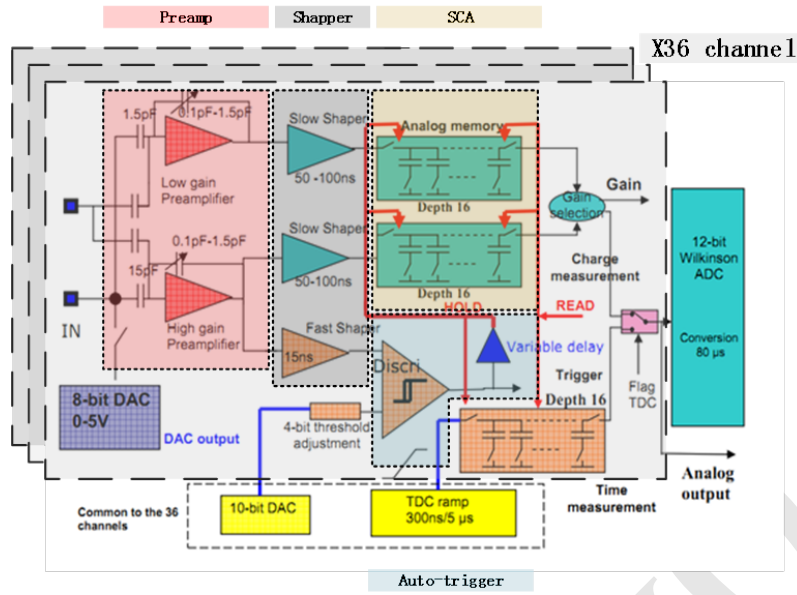

Figure 5.8: Schematic of the SPIROC2b ASIC chip.

As Particle Flow Algorithm (PFA) is being considered, high granularity requirement need be meet. Granularity of cells in ECAL need be finer than 10mm therefore a large amount of channels need be readout. So multiple-channels-readout-chip is considered.

Electronics consists of two parts: Front-End and Back-End. The Front-End-Electronics (FEE) is embedded into the layers of ECAL. It performs amplification, auto-triggering, digitization and zero-suppression, with local storage of data between the working phases. The Back-End-Electronics play the role of collecting data and configuring chip before system running.

Several studies and existing calorimeter readout electronics have shown that one can obtain optimized energy resolutions using a preamplifier-shaper and digitizing the pulse at peak. For instance, a preamp-shaper-SCA structure of analog circuit applied on ILC HCAL which implemented in ASIC. A similar approach can be applied at CEPC-ECAL. An ASIC named SPIROC2b is considered in present stage. The analog part is schematically depicted in Figure 5.8.

The basic principle consists of a readout chain with an amplifier-shaper using a RCn-CRp filter delivering a pulse length of about 50-200ns duration for a SiPM pulse signal. This signal is also shaped by a fast shaper in the same time to generate fast and narrow pulse for discriminating. Then the discriminator gives the trigger to Switched-Capacitor-Array (SCA) for locking the peak value of slow-shaped signal. The locked voltage value is corresponding to the charge that circuit received. A 12bits Wilkinson ADC is used for digitizing analog voltage in SCA. Future detailed implementations of the calorimeter front-end electronics for CEPC is still considered using ROC series ASIC but newer version.

The maximum data rate can be estimated as follows. Assuming signal keep coming consistently, SPIROC2b will be continuously switched between three states called Acquisition, AD Converting and Readout. Only in Acquisition state can SPIROC2b receive signal from SiPM and stored in SCA in the rate of about 5MHz. Another two states should be seen as "dead-time" status. There is 16 depth in SCA, so 4µs for Acquisition, accord-

ing to measurement, ~ 4 ms for ADC & Readout. So data rate is 16 events per 4ms which equals to 4 kHz. Each fulfilled data packaged is 2 Kbytes in size.

More chip in one layer will multiply the duration of Readout. Assuming that there are 4 chips in one layer. So there is 16ms for Readout. Maximum events rate is reduced to 1kHz and leads to about a transmission of 5Mbyte/s. This can easily be managed with 100M links.

The power consumption in the front-end will be dominated by ASIC and more specifically by analog part of ASIC. Opening all modules, one SPIROC2b is consuming 250.8mW of which about 150mW is consumed by analog part. In actual use, most of cycle is ADC and Readout. It leads to about 150mW power consumption per chip and 4mW per channels.

The electronic calibration and cosmic ray test have been done. From these electronic calibration we have obtained that the noise of readout system is 46fC in RMS and high gain and low gain is 151/pC and 10.3/pC while maximum ADC range is 4096. So dynamic range that from 100fC-300pC of readout system is measured by electronic method. Cosmic ray results shows that the system can distinct MIPs signal from pedestal well and figure out that about 1pC.

5.4 Hadronic Calorimeter for Particle Flow Approach

5.4.1 Introduction

High-granularity hadronic calorimeter concept is to play an essential role in PFA-based experiments such as CEPC. It allows to separate the deposits of charged and neutral hadrons and to precisely measure the energy of the neutrals. The contribution of the neutrals to the jet energy, around 10% on average, fluctuates in a wide range from event to event, and the accuracy of the measurement is the dominant contribution to the particle flow resolution for jet energies up to about 100 GeV. For higher energies, the performance is dominated by confusion, and both topological pattern recognition and energy information are important for correct track cluster assignment. High-granularity hadronic calorimeter is thus needed to achieve excellent jet energy resolution.

HCAL are sampling calorimeters with steel as absorber and scintillator tiles or gaseous devices with embedded electronics for the active part. The steel was chosen due to its rigidity which allows to build self-supporting structure without auxiliary supports (dead regions). Moreover, the moderate ratio of hadronic interaction length ($\lambda_I = 17$ cm) to electromagnetic radiation length ($X_0 = 1.8$ cm) of iron, allows a fine longitudinal sampling in terms of X_0 with a reasonable number of layers in λ_I , thus keeping the detector volume and readout channel count small. This fine sampling is beneficial both for the measurement of the sizable electromagnetic energy part in hadronic showers as for the topological resolution of shower substructure, needed for particle separation.

The active detector element has very finely segmented readout pads, with 1×1 cm² size, for the entire HCAL volume. Each readout pad is read out individually, so the readout channel density is approximately $4 \times 10^5/\text{m}^3$. For the entire HCAL, with ~ 100 m³ total volume, the total number of channels will be 4×10^7 which is one of the biggest challenges for the HCAL system. On the other hand, simulation suggests that, for a calorimeter with cell sizes as small as 1×1 cm², a simple hit counting is already a good energy measurement for hadrons. As a result, the readout of each channel can be greatly

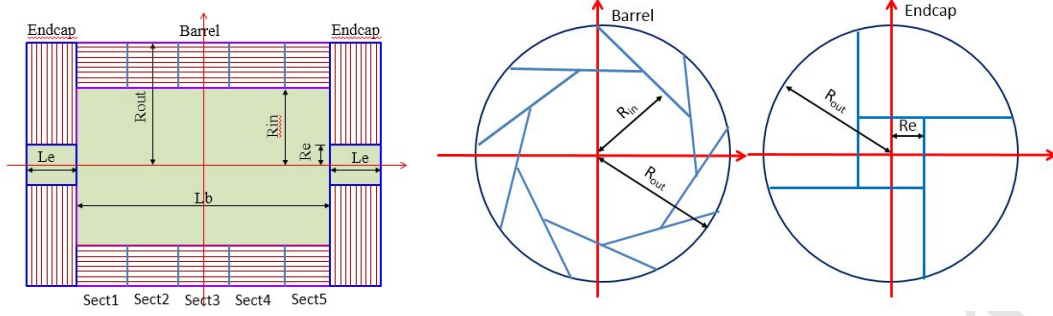

Figure 5.9: HCAL layout in Y-Z plane (left plot), HCAL Barrel layout in X-Y plane (middle plot) and HCAL Endcap layout in X-Y plane (right plot).

simplified and just record 'hit' or 'no hit' according to a single threshold (equivalent to a '1-bit' ADC). A hadron calorimeter with such kind of simplified readout is called a Digital Hadron Calorimeter (DHCAL). In a DHCAL, each readout channel is used to register a 'hit', instead of measure energy deposition, as in traditional HCAL. In this context, gas detectors (such as RPC, GEM) become excellent candidates for the active element of a DHCAL. Another technology option is Analog Hadron Calorimeter (AHCAL) which is based on scintillator with SiPM as active sensor.

A drawing of the HCAL structure is shown in Figure 5.9, the barrel part is made of 5 independent and self-supporting wheels along the beam axis. The segmentation of each wheel in 8 identical modules is directly linked with the segmentation of the ECAL barrel. A module is made of 40 stainless steel absorber plates with independent readout cassettes inserted between the plates. The absorber plates consist of a total of 20 mm stainless steel: 10 mm absorber from the welded structure and 10 mm from the mechanical support of the detector layer. Each wheel is independently supported by two rails on the inner wall of the cryostat of the magnet coil. The cables as well the cooling pipes will be routed outside the HCAL in the space left between the outer side of the barrel HCAL and the inner side of the cryostat.

5.4.2 Semi-Digital Hadronic Calorimeter (SDHCAL)

5.4.2.1 Introduction

For the CEPC, a SDHCAL based on gaseous detector is proposed. This is motivated by the excellent efficiency and very good homogeneity the gaseous detectors could provide. Another important advantage of gaseous detectors is the possibility to have very fine lateral segmentation. Indeed, in contrast to scintillator tiles, the lateral segmentation of gaseous devices is determined by the readout electronics and not by the detector itself. Active layer thickness is also of importance for what concerns the CEPC hadronic calorimeter to be placed inside the magnetic field. Highly efficient gaseous detectors can indeed be built with a thickness of less than 3 mm. Other detectors could achieve such performance. However, gaseous detectors have the advantage of being cost-effective and discharge free. They are also known for their fast timing performance which could be used to perform 4D construction of the hadronic showers. Such a construction can improve on hadronic showers separation by better associating the energy depots belonging to the same shower from

those of other showers. It can also improve on the energy reconstruction by identifying the delayed neutrons and assigning them a different weight.

To obtain excellent resolution of hadronic shower energy measurement a binary read-out of the gaseous detector is the simplest and most effective scenario. However, a lateral segmentation of a few millimeters is needed to ensure good linearity and resolution of the reconstructed energy. Such a lateral segmentation leads to a huge number of electronic channels resulting in a complicated readout system design and a too large power consumption. $1 \times 1 \text{ cm}^2$ cells are found to be a good compromise that still provides a very good resolution at moderate energies. However, simulation studies show that saturation effects are expected to show up at higher energies ($> 40 \text{ GeV}$). This happens when many particles cross one cell in the center of the hadronic shower. To reduce these effects, the choice of multi-threshold electronics (Semi-Digital) readout is chosen to improve on the energy resolution by exploiting the particle density in a more appropriate way. These elements were behind the development of a Semi-Digital Hadronic CALorimeter (SDHCAL) that we propose to equip one of the CEPC future experiments.

Even with a $1 \times 1 \text{ cm}^2$ lateral granularity of the readout system, a huge number of electronic channels is still needed. This has two important consequences. The first is the power consumption and the resulting increase of temperature which affects the behavior of the active layers. The other consequence is the number of service cables needed to power, read out these channels. These two aspects can deteriorate the performance of the HCAL and destroy the principle of PFA if they are not addressed properly.

The R&D pursued by the CALICE SDHCAL groups has succeeded to pass almost all the technical hurdles of the PFA-based HCAL. The SDHCAL groups have succeeded to build the first technological prototype [12] of these new-generation calorimeters with 48 active layers of GRPC, 1 m^2 each. The prototype validates the concept of high-granularity gaseous detector and permits to study the energy resolution of hadrons one can obtains with such calorimeter. Figure 5.10 shows the energy resolution of SDHCAL with different number of layers using test beam data collected at CERN. It indicates that SDHCAL with 40 layers yield descent performance with pion energy up to 80 GeV which is suitable for CEPC detector.

A baseline detector of SDHCAL has been designed with 40 layers in total. Each layer contains 20 mm thick stainless steel, 3 mm thick GRPC and 3 mm for readout electronics with $1 \times 1 \text{ cm}^2$ readout pads on PCB board.

In order to find out an appropriate option for the active detector of the SDHCAL, two parallel detector schemes, the Glass Resistive Plate Chamber (GRPC) and the Thick Gaseous Electron Multiplier (THGEM) are proposed for the active layers of the SDHCAL.

5.4.2.2 GRPC based SDHCAL

The GRPC scheme The structure of GRPC proposed as an active layer of the HCAL proposed for CEPC is shown in Figure 5.11. It is made out of two glass plates of 0.7 mm and 1.1 mm thickness. The thinner is used to form the anode while the thicker forms the cathode. Ceramic balls of 1.2 mm diameter are used as spacers between the glass plates. The balls are glued on only one of the glass plates. In addition to those balls, 13 cylindrical fiber-glass buttons of 4 mm diameter are also used. Contrary to the ceramic balls the buttons are glued to both plates ensuring thus a robust structure. Special spacers (ceramic balls) were used to maintain uniform gas gap of 1.2 mm. Their number and distribution were optimized to reduce the noise and dead zones (0.1%).

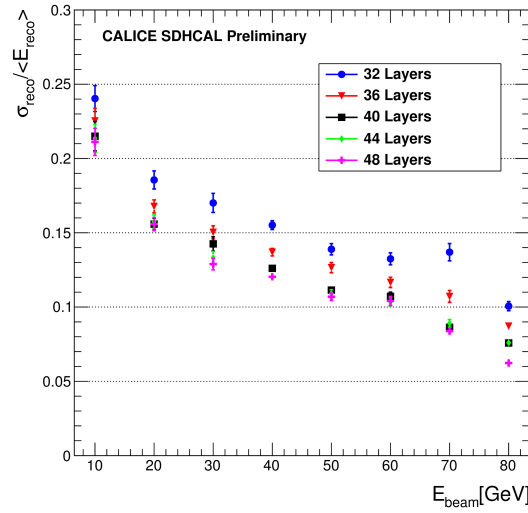

Figure 5.10: The energy resolution of SDHCAL with different number of layers using beam test data collected at CERN.

The distance between the spacers (10 cm) was fixed so that the deviation of the gap distance between the two plates under the glass weight and the electric force does not exceed 45 microns. The choice of these spacers rather than fishing lines was intended to reduce the dead zones (0.1%). It was also aimed at reducing the noise contribution observed along the fishing lines in standard GRPC chambers. The gas volume is closed by a 1.2 mm thick and 3 mm wide glass-fiber frame glued on both glass plates. The glue used for both the frame and the spacers was chosen for its chemical passivity and long term performance. The resistive coating on the glass plates which is used to apply the high voltage and thus to create the electric field in the gas volume was found to play important role in the pad multiplicity associated to a mip [13]. A product based on colloids containing graphite was developed. It is applied on the outer faces of the two electrodes using the silk screen print method, which ensures very uniform surface quality. The measured surface resistivity at various points over a 1m² glass coated with the previous paint showed a mean value of 1.2 MΩ/cm² and a ratio of the maximum to minimum values of less than 2 ensuring a good homogeneity of the detector.

Another important aspect of this development concerns the gas circulation within the GRPC taking into account that for the CEPC SDHCAL, gas outlets should all be on one side. A genuine system was proposed. It is based on channeling the gas along one side of the chamber and releasing it into the main gas volume at regular intervals. A similar system is used to collect the gas on the opposite side. A finite element model has been established to check the gas distribution. The simulation confirms that the gas speed is reasonably uniform over most of the chamber area. The GRPC and its associated electronics are housed in a special cassette which protects the chamber and ensures that the readout board is in intimate contact with the anode glass. The cassette is a thin box consisting of 2.5 mm thick stainless steel plates separated by 6 mm wide stainless steel spacers. Its plates are also a part of the absorber.

The electronics board is assembled thanks to a polycarbonate spacer which is also used to fill the gaps between the readout chips and to improve the overall rigidity of the detector. The electronics board is fixed on the small plate of the cassette. Thanks to tiny screws and

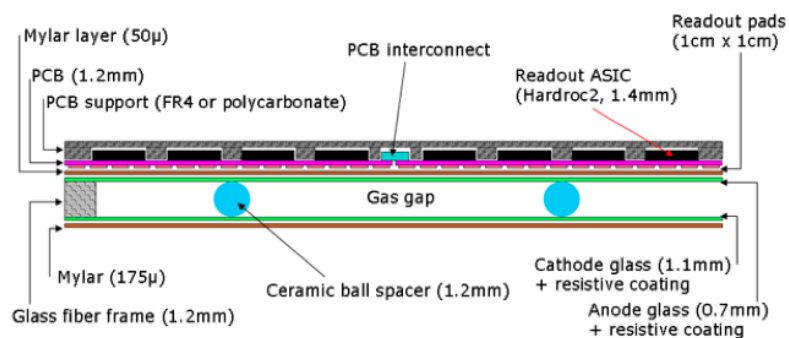

Figure 5.11: Cross sectional view of an active layer with GRPC and readout layer.

the new set is fixed on the other plate which hosts the detector and the spacers. The whole width of the cassette is 11 mm with only 6 of them corresponding to the sensitive medium including the GRPC detector and the readout electronics.

GRPC technological prototype An SDHCAL prototype fulfilling the efficiency, robustness and the compactness requirements of the future PFA-based leptonic collider experiments [12] was built. 48 cassettes as the one described above were built. They fulfilled a stringent quality control. It is worth mentioning that 10500 HR ASICs were produced and tested using a dedicated robot for this purpose. The yield was found to be higher than 92%. The ASICs were then fixed on the PCBs to make a 1m² and itself fixed on the cassette cover once successfully tested. The cassettes were inserted in a self-supporting mechanical structure that was conceived and built in collaboration with the Spanish group of CIEMAT. The structure is made of Stainless Steel plates of 1.5 cm each. The plates were machined to have an excellent flatness and well controlled thickness. The flatness of the plates was measured using a laser-based interferometer system. It was found that the flatness of the plates are less than 500 microns. In April 2012 the prototype was exposed to pion, muon, electron beams of both the PS and the SPS of CERN Figure (5.12). The data were collected continuously in a triggerless mode. Figure 5.13 shows the efficiency (left) and pad multiplicity (right) of the prototype's GRPC chambers measured using the muon beam. Figure 5.14 shows a display of two events collected in the SDHCAL. One is a produced by a pion interaction (left) and the other by an electron interaction (right).

The SDHCAL prototype results obtained with a minimum data treatment (no grain correction) show clearly that excellent linearity and good resolution [14] could be achieved on large energy scale as can be shown in Figure 5.15 where results obtained in two different beam lines are obtained using the same detector configurations. Useless to mention that the high granularity of the SDHCAL allows one to study thoroughly the hadronic showers topology and to improve on the energy resolution by, among others, separating the electromagnetic and the hadronic contribution. The separation between close-by showers will also get big benefit thanks to the high granularity on the one hand and to the very clean detector response ($< 1 \text{ Hz/cm}^2$) on the other hand. The results obtained with the the SDHCAL [15] confirm the excellent efficiency of such separation thanks to the SDHCAL performance.

The quality of data obtained during several campaigns of data taking at the CERN PS and SPS beam lines validates completely the SDHCAL concept. This is especially encouraging since no gain correction was applied to the electronics channels to equalize

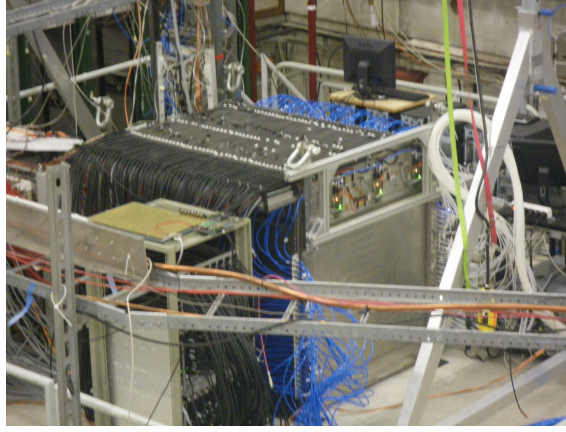

Figure 5.12: The SDHCAL prototype in beam test at CERN.

their response. Still, improvement was further achieved by applying gain and threshold correction schemes in terms of the calorimeter response homogeneity.

A digitizer describing the response of the GRPC within the SDHCAL was developed [16]. It allows to study the SDHCAL behavior in a realistic manner in the future experiments.

In parallel to the prototype construction, a single cassette was tested in a magnetic field of 3 Tesla (H2 line at CERN) applying the power-pulsed mode. The TB results [17] indicated clearly that the use of the power-pulsed mode in such a magnetic field is possible. The behavior of the detector (efficiency, multiplicity..) was found to be similar to those obtained in the absence of both the magnetic field and the power-pulsed mode.

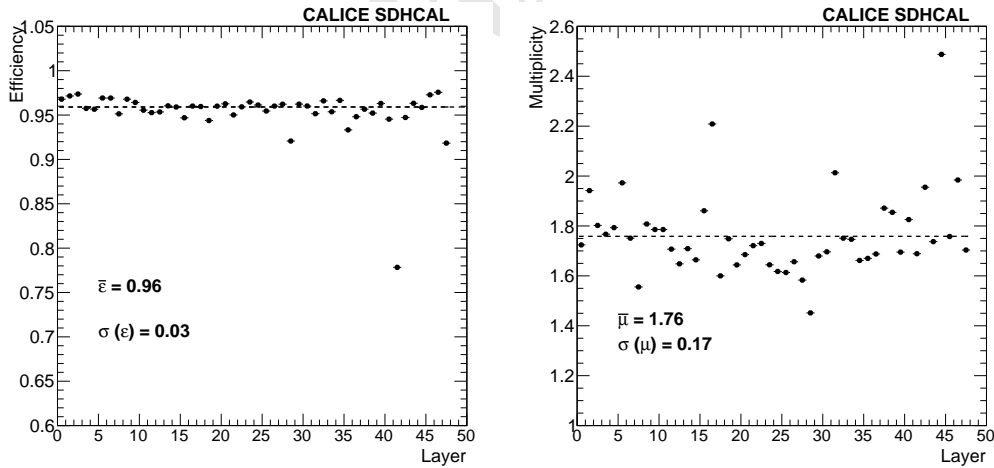

Figure 5.13: Left: Efficiency of the GRPC detectors of the SDHCAL. Right: the pad multiplicity of the GRPCs. One third of the chamber 42 was not instrumented.

Current SDHCAL R&D Large GRPC of 1m^2 were developed and built for the technological prototype. However, larger GRPC are needed in the SDHCAL proposed for future leptonic collider experiments. These large chambers with gas inlet and outlet on one side need a dedicated study to guarantee a uniform gas gap everywhere notwithstanding the

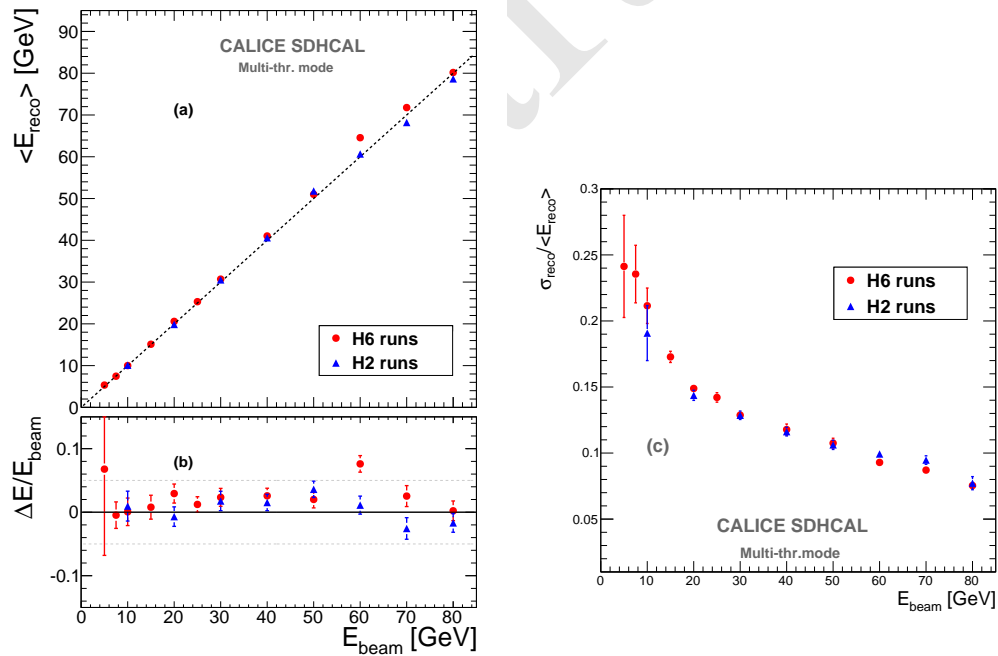

Figure 5.15: Left: a) Reconstructed energy of the hadronic showers collected in both H2 and H6 SPS beamlines. b) the relative deviation of the reconstructed energy with respect to the beam energy. Right: Relative energy resolution of the reconstructed hadronic shower. Pion beam of H6 beamline is largely contaminated by protons at high energy (>50 GeV).

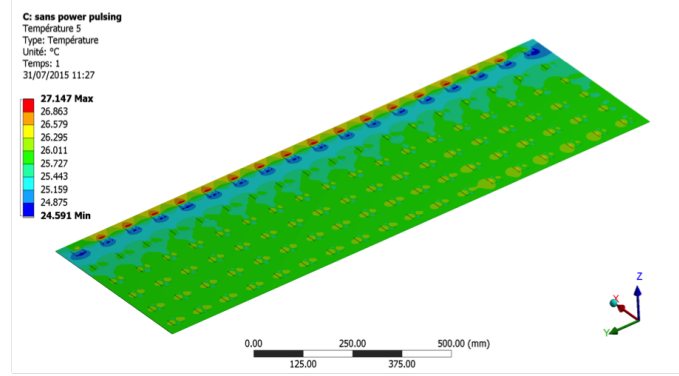

Figure 5.16: Temperature distribution in an active layer of the SDHCAL operated with no power-pulsing. The cooling system is made of a circulating water inside copper tubes in contact with the ASICs.

angle of the plate. It is necessary also to ensure an efficient gas distribution as it was done for the 1m² chambers. To obtain this different gas distribution systems were studied. A new scheme with two gas inlets and one outlet was found to ensure an excellent homogeneity of the gas distribution. This system will be used in the near future to build large detectors exceeding 2m².

To cope with the heating produced by the embedded readout system in case of limited or even the absence of use of the Power Pulsing system, a new active cooling system is being studied. Figure 5.16 shows a study of a water-based cooling system to absorb the excess of heat in the SDHCAL. The cooling system is very simple but very effective as well. It allows to keep the average temperature as well as the temperature dispersion of the GRPC well under control.

5.4.2.3 THGEM-based DHCAL

The THGEM scheme The THGEM can be built in large quantities at low cost, which might make them suitable for the large CEPC HCAL. THGEM detectors can provide flexible configurations, which allow small anode pads for high granularity. They are robust and fast, with only a few nano-seconds rise time, and have a short recovery time which allows a higher rate capability compared to other detectors. They are operated at a relatively low voltage across the amplification layer with stable high gain. The ionisation signal from charged tracks passing through the drift section of the active layer is amplified using a single layer or WELL-type THGEM structure. The amplified charge is collected at the anode layer with pads at zero volts. As the HCAL is located within the coil, WELL-THGEM, a single layer structure with thinner thickness, as shown in Fig. 5.17, can be considered as the sensitive medium, to keep the HCAL compact.

Digital readout has been proposed to limit the total amount of data, which simplifies the data treatment without comprising the energy resolution performance. The readout electronics of the DHCAL will be integrated into the sensitive layer of the system, thus minimising dead areas. Large electronics boards are assembled together to form extralarge boards before being attached to the THGEM. The board assembly will utilise a mechanical structure made of 4 mm stainless steel plate. In addition, to keep the HCAL as compact as possible, the fully equipped electronic boards are designed to be less than 2 mm thick in total.

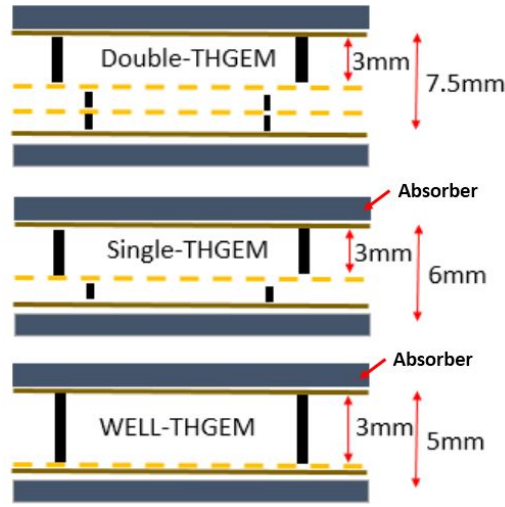

Figure 5.17: Schematic of three different types of THGEMs, eg. doubly-THGEM, single-THGEM and well-THGEM.

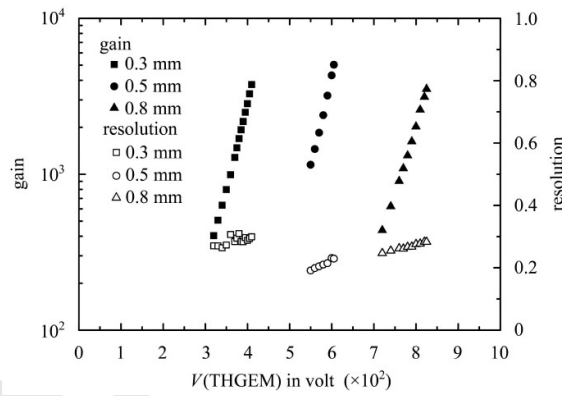

Figure 5.18: Gain and energy resolution of THGEM detector obtained with ^{55}Fe .

A THGEM based detector for DHCAL has been designed with 40 layers in total. Each layer contains 2.0 cm thick stainless steel, 0.8 cm thick THGEM and readout electronics with $1 \times 1 \text{ cm}^2$ readout pads. As THGEM production technology matures, the maximum area of THGEM is limited only by the size of the CNC drilling area. Its low price, robustness against occasional discharges, high gain and count rate capability of up to 10MHz/cm^2 make THGEM very attractive for building the DHCAL. As illustrated in Fig. 5.17, the total thickness of the sensitive medium is 5 mm, which consists of 3 mm drift gap, 1 mm transfer gap and 1 mm induction gap. The absorber between the active layers is made of 20 mm thick stainless steel. The thickness of the readout electronics board is about 3 mm, and the total thickness of a single sensitive layer is less than 10 mm. Each layer corresponds to about 1.2 radiation length and 0.65 nuclear interaction length. The whole DHCAL detector is evenly divided into 40 layers, with a total stainless steel absorber thickness of 4.7 nuclear interaction lengths.

THGEM prototype A THGEM with an area of $40 \times 40 \text{ cm}^2$ has been successfully fabricated, as shown in Fig. 5.19, and a gain of 2×10^5 has been achieved with a double

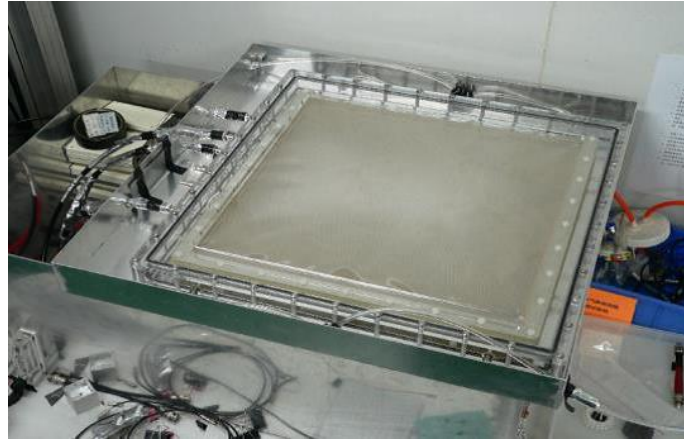

Figure 5.19: A THGEM was produced with size of $40 \times 40 \text{ cm}^2$.

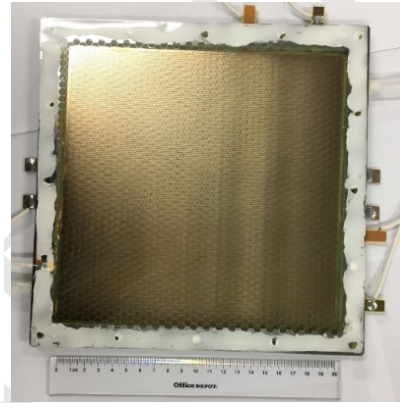

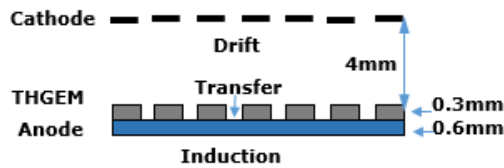

Figure 5.20: The schematic diagram of the WELL-THGEM (left plot) and a $20\text{cm} \times 20\text{cm}$ WELL-THGEM detector (right plot).

THGEM, with an energy resolution of about 20%. The THGEM produced has the following features:

1. standard PCB processes are used, which keeps the cost low;
2. excellent performance in terms of energy resolution, gas gain and stability (as shown in Fig. 5.18);
3. Rim around the hole formed by full-etching process, the size of which can be varied between $10 \mu\text{m}$ and $90 \mu\text{m}$, as depicted in Fig. 5.18 - this allows adjustment according to gas requirements.

Fig. 5.20 shows the schematic diagram of a new THGEM detector, where a micro-plate directly attached to the readout plate, since the micro-porous structure similar to a well, known as the well-type THGEM (WELL-THGEM). This structure contains of a single-layer THGEM, so that the thickness of detector can be reduced to $4 \sim 5 \text{ mm}$, and the total thickness of the detector including ASIC electronics could be lowered to about 6 mm. A $20\text{cm} \times 20\text{cm}$ WELL-THGEM detector using thin-type THGEM have been developed as shown in the right plot of Fig. 5.20

In addition, Researches on large THGEM detectors have been carried out. Single THGEM detectors and Well-THGEM detectors are being developed to reduce detector

instability and inefficiency. Gas recycling systems are built to lower gas consumption and pollution. The achieved THGEM detection rate of 1 MHz/cm^2 with efficiency greater than 95% already meets the CEPC requirements.

THGEM digital readout system A MICRO-mesh gaseous structure Read-Out Chip (MICROROC), which is developed at IN2P3 by OMEGA/LAL and LAPP microelectronics groups was used to read out the THGEM-based SDHCAL. The MICROROC is a 64-channel mixed-signal integrated circuit based on 350 nm SiGe technology. Each channel of the MICROROC chip contains a very low noise fixed gain charge preamplifier which is optimized to cover a dynamic range from 1 fC to 500 fC and allow a input detector capacitance of up to 80 pF, two gain-adjustable shapers, three comparators for triple-threshold readout and a random access memory used as a digital buffer. Otherwise, it have a 10-bit DAC, a configuration register, a bandgap voltage reference, a LVDS receiver shared by 64 channels etc. A 1.4 mm total thickness is achieved by using the Thin Quad-Flat Packaging (TQFP) technology.

5.4.3 AHCAL based on Scintillator and SiPM

A high-granularity hadronic calorimeter plays an essential role in PFA-based experiments such as CEPC. It allows separation of the energy deposits from charged and neutral hadrons. The contribution of the neutrals to the jet energy, around 10% on average, fluctuates over a wide range from event to event. The AHCAL (Analog Hadron CALorimeter) is a sampling calorimeter with steel as the absorber and scintillator tiles with embedded electronics. The moderate ratio of hadronic interaction length ($I=17\text{cm}$) to electromagnetic radiation length ($X_0 = 1.8 \text{ cm}$) of steel, allows a fine longitudinal sampling in terms of X_0 with a reasonable number of layers.

Various calorimetry options are being developed to address challenges from the stringent performance requirements on future lepton collider experiments for precision measurements of the Higgs boson and for searches of physics beyond Standard Model. Within the CALICE collaboration, a large technological prototype [18] using scintillator tiles and SiPMs is currently being built to demonstrate the scalability to construct a final detector via automated mass assembly. The outcome of CALICE-AHCAL R&D activities can be an essential input for the conceptual design of the hadron calorimeter system at the future lepton colliders.

5.4.3.1 AHCAL geometry and simulation

The AHCAL will consist of 40 sensitive and absorber layers, and the total thickness is about 100cm. The AHCAL barrel consists of 32 super module, each super module consists 40 layers, figure 5.21 shows the AHCAL structure. Figure 5.22 shows the single layer structure of AHCAL. The scintillator tiles wrapped by reflective foil are used as sensitive medium, interleaved with stainless steel absorber. The thickness of active layer including the scintillator and electronics is about 4mm 5mm.

The structure of scintillator tiles is shown in Figure 5.23. A dome-shaped cavity was processed in the center of the bottom surface of each tile by injection molding technology. The diameter and height of cavity [19] are 6mm, 1.5mm, respectively, as shown in Figure 5.23 (right). Good response uniformity and low dead area will be achieved by the design of cavity. More optimizations of cavity structure will be done by Geant4 simulation.

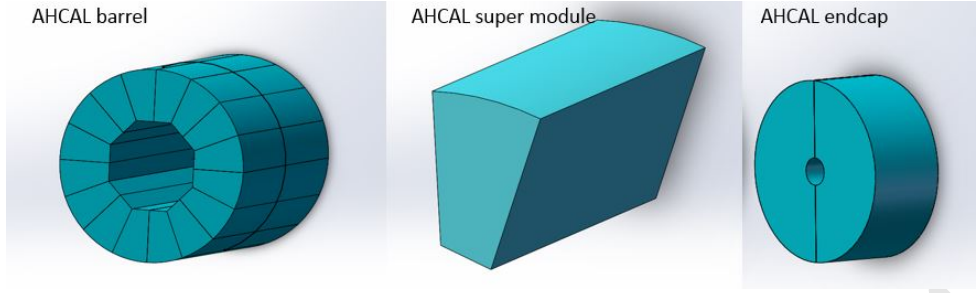

Figure 5.21: The layout of AHCAL barrel (left) and endcap regions (right), the middle plot shows a super module of AHCAL.

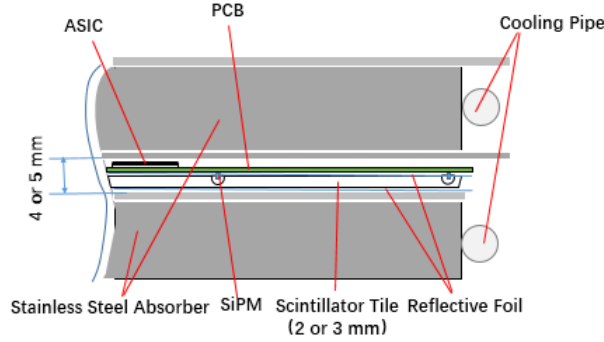

Figure 5.22: Cross sectional view of a single layer of AHCAL.

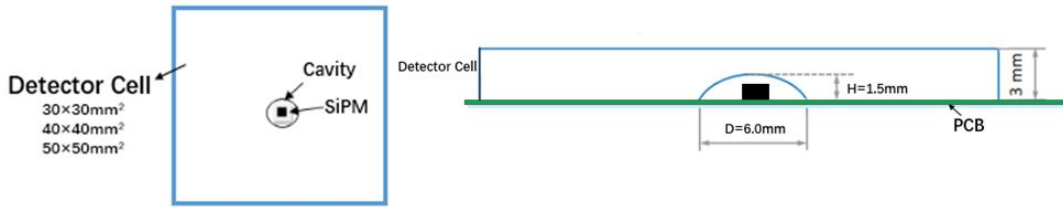

Figure 5.23: Top view of a detector cell (left) and cross sectional view of a detector cell with a dome-shaped cavity (right)

The AHCAL prototype detector was simulated by Geant4. The detector model used here was CEPC_v1 detector model. The geometry information was extracted by Mokka at runtime and the generated events were stored in Slcio, which contains primary information regarding the energy deposition, hit position, time and Monte Carlo particle causing the energy deposition. The ECAL was simulated with 30 layers, and the HCAL has 40 active layers interleaved with 20 mm stainless steel as absorber plates. Each active layer consists of plastic scintillator (3mm) and readout layer (2mm PCB), detector cell size is $30 \times 30 \times 3 \text{ mm}^3$, as shown in Figure 5.24.

$$E_{REC} = a \times E_{ECAL} + b \times E_{HCAL} \quad (5.3)$$

In order to obtain the resolution of calorimeters (ECAL and AHCAL) as shown in figure 5.24, the energy reconstruction formula 5.3 is employed [20], the coefficients a and b in this formula represent ECAL and HCAL calibration constant, respectively. After optimization, the calibration constants are $a=44.4$ and $b=44.2$ respectively which were corrected by

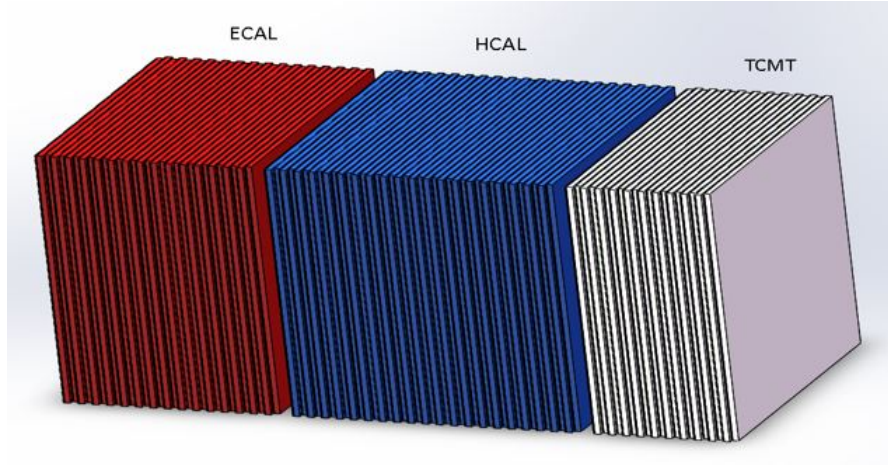

Figure 5.24: The structure of simulated calorimeters which is a part of the simplify geometry. Red part is the Silicon ECAL, Blue part is the scintillator AHCAL.

energy of 60GeV. Calibration constants can correct the energy leakage from the calorimeters. So one can use formula 5.4 [20] to calculate the resolution. The energy resolution result is shown in figure 5.25.

$$\frac{\sigma}{E} = \frac{p_0}{\sqrt{E}} + p_1 \quad (5.4)$$

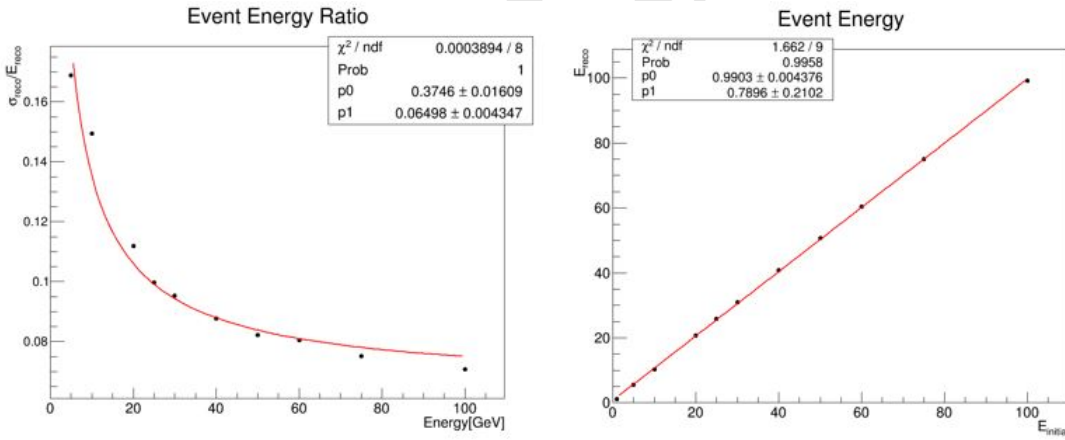

Figure 5.25: Left figure is energy resolution, right figure is the result of reconstruction energy linearity

5.4.3.2 Plastic Scintillator detector cell design and test

According to study of CALICE collaboration, $30 \times 30\text{mm}^2$ scintillator detector cell size is an optimal size. The simulation results of CALICE collaboration [21] also suggest that it is possible to use the detector cells of larger sizes. It will reduce nearly half electronics channels by using $40 \times 40\text{mm}^2$ size detector cell instead of $30 \times 30\text{mm}^2$ size. Therefore, the construction costs can be greatly reduced if the larger detector cells can meet the physics requirements. Two larger sizes of detector cells were considered. Four kinds of scintillator tiles with different sizes were fabricated and tested.

The SiPM is soldered onto a readout Printed Circuit Board (PCB) and the scintillator tile wrapped by ESR reflective foil is directly glued onto the PCB. A cavity design pro-

vides enough space for the SiPM package and improves collection efficiency of the light produced by incident particles penetrating the tile at different positions.

A strongly non-uniform tile response can lead to a distortion of the energy reconstruction in a complete calorimeter, and also compromises the calibration of the detector cells based on single particle signals. Three different sizes tiles ($30\times30\times3\text{mm}^3$, $30\times30\times2\text{mm}^3$ and $50\times50\times3\text{mm}^3$) were tested by the Hamamatsu MPPC S12571-025P and S13360-025PE. The spatial distribution of photon equivalents number (p.e.) with different detector cell areas are shown in Figure 5.26. The result shows that the number of p.e. in the center area is slightly larger than that of the surrounding area. The 100% of the cell signal amplitude is within 10% deviation from the mean value for $30\times30\text{mm}^3$ cell. The 94% of the cell signal amplitude is within 10% deviation from the mean value for $50\times50\times3\text{mm}^3$ cell. The three detector cells show good response uniformity.

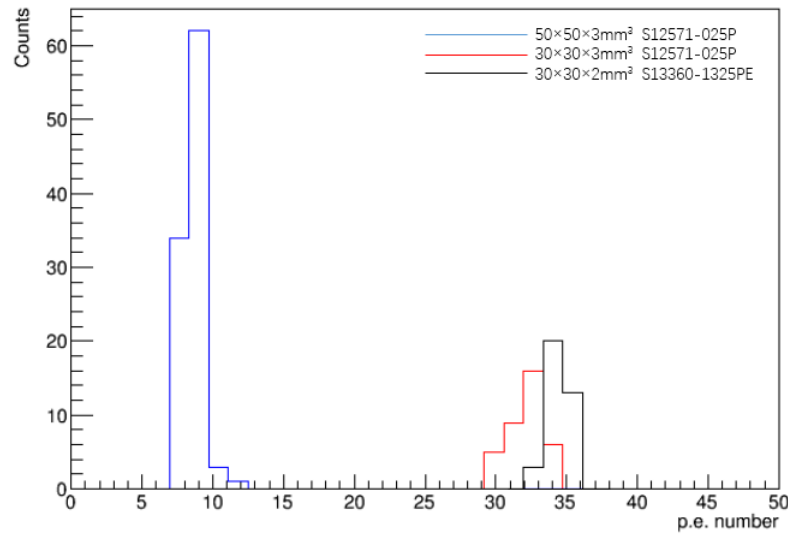

Figure 5.26: The uniformity measurement result of $30\times30\times3\text{mm}^3$, $50\times50\times3\text{mm}^3$ and $30\times30\times2\text{mm}^3$ detector cell

Seven detector cells of different sizes, polishing methods and wrapping foil types were measured. The larger the area of the cell is, the less p.e. are detected, and the results of same size cells varied greatly because of the polishing methods.

The detection efficiency of $30\times30\times3\text{mm}^3$ and $50\times50\times3\text{mm}^3$ were measured by the cosmic ray test. The detection efficiency of $30\times30\times3\text{mm}^3$ and $50\times50\times3\text{mm}^3$ cells are 99%, 98.2%, respectively. According the cosmic-ray test result, the detection efficiency of $30\times30\times2\text{mm}^3$ with S13360-025PE MPPC also can reach to 98%.

The good response uniformity and high detection efficiency results indicate that scintillator detector cells are acceptable for AHCAL. The size of $30\times30\times3\text{mm}^3$ detector cell is the baseline of AHCAL and more optimization of the detector cell size will be done by the simulation and experiment.

5.4.3.3 Development of SiPM

Several kinds of SiPM were developed by Hamamatsu and other company, they have been used for scintillator ECAL. The SiPM with epitaxial quenching resistors (EQR SiPM) is one of the main SiPM technologies under development in China. As shown in Figure 5.27, each APD cell (pixel) forms a high electric field, composing an enriched region be-

tween N-type epitaxial silicon substrate and P++ cap layer, and it employs the un-depleted region in the epitaxial silicon layer below P/N junction as the quenching resistor. Compared to conventional SiPM configurations that employ poly-silicon quenching resistors on the device surface, it is easier to achieve high density and small micro APD cells, thus obtaining a small junction capacitor; It's expected to have short recovery time and high counting rate for EQR SiPM.

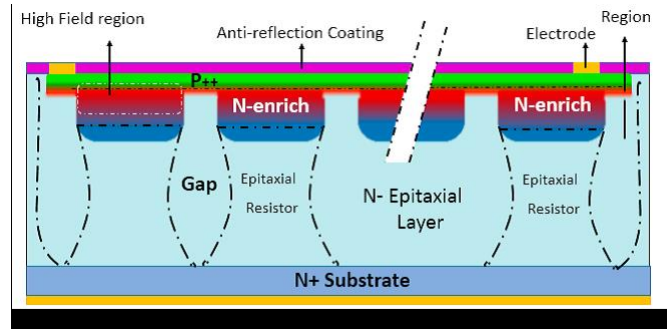

Figure 5.27: Schematic structure of EQR SiPM; APD cell consists of N-enriched regions forming high electric fields between the N-type epitaxial silicon wafer and the P++ surface layer, the un-depleted region in the epitaxial silicon layer below the P/N junction as the quenching resistor, and the APD cells are isolated from each other by the Gap depletion region.

5.4.3.4 Electronics and DAQ

Front-end electronics ASIC: High-density electronics is indispensable to instrumentation of high-granularity calorimetry. An ASIC chip named SPIROC, developed by the OMEGA group, is capable to handle 36 SiPMs. For each channel, it can be operated in an auto-trigger mode and has a dual-gain charge preamplifier with high dynamic range. It allows to measure the charge from 1 to 2000 photo-electron and the time within 1 ns using a 12-bit digitizing circuit. With one 8-bit 5V input DAC per channel, the bias voltage for each SiPM can be adjusted to reach its optimum. In each channel, there are 16 analogue memory cells that can buffer both charge and timing signals to be digitized afterwards consecutively. The digitization circuit is shared for both charge and timing measurements to minimize the power consumption, which needs to be as low as $25 \mu W$ per channel.

5.4.3.5 Cooling system

Inside active layer, the total power consumption of SPIROC ASIC chip and SiPM is about 5 mW/channel [22]. The scintillator detector cell size is $30 \times 30 \text{ mm}^2$, and the total channel number is about 5 million. For whole AHCAL, the total power consumption from ASIC chip is about 30kW. The copper cooling water pipes is expected to embed in stainless steel absorber. It is shown in layer structure as in figure 5.22. Detailed design and optimization of a cooling system is needed.

5.5 Dual-readout calorimetry

5.5.1 Introduction

The dual-readout approach envisages designing a combined, homogeneous, detector with excellent performance for both electromagnetic and hadronic particle showers.

Till now, the performance obtained in hadronic energy measurements has been by far worse than for the electromagnetic ones, since showers from single hadrons or jets develop an electromagnetic component, from π^0 and η production, that exhibits large event-by-event fluctuations and dependence on the particle type and energy [23].

As a matter of fact, the *em* fraction depends on the kind of particle initiating the shower (e.g., π , K , p) since, for example, impinging π^\pm mesons can undergo a charge-exchange reaction with a nucleon as first interaction and generate a pure *em* shower, while a p cannot do that due to baryon number conservation.

Moreover, since π^0 production happens at any stage of shower development, the $\langle f_{em} \rangle$ increases with the energy as well as with the depth ("age") of the shower.

The *em* and *non-em* components of a hadronic shower are normally sampled with very different sensitivity, producing large differences in the measured signals, heavily affecting the energy resolution capability.

To overcome the problem two methods have been exploited: compensation and dual readout (DR). The first relies on equalising the detector response to electromagnetic (*e*) and non-electromagnetic (*h*) shower particles (i.e. $h/e = 1$), but this requires a fixed ratio of absorber-to-sensor volumes, which limits the electromagnetic energy resolution, and the integration of the signals over large volumes and long times, to increase the response to the *h* component. The dual-readout method avoids these limitations by directly measuring f_{em} on an event-by-event basis. The showers are sampled through two independent processes, namely scintillation (*S*) and Čerenkov (*C*) light emissions. The former is sensitive to all ionizing particles, while the latter is produced by highly relativistic particles only, almost exclusively found inside the *em* shower component. By combining the two measurements, energy and f_{em} of each shower can be simultaneously reconstructed. The performance in hadronic calorimetry may be boosted toward its ultimate limit.

The results obtained so far with prototypes, support the statement that fibre-sampling DR calorimeters may reach resolutions of the order of $10\%/\sqrt{E}$ for *em* showers and around $30 - 40\%/\sqrt{E}$ for hadronic showers, coupled with strong standalone particle-ID capabilities. This would allow $W \rightarrow jj$ separation from $Z \rightarrow jj$ by invariant mass, high-precision missing three-momentum reconstruction by subtraction, $e-\mu-\pi$ separation and particle tagging.

While the dual-readout concept has been extensively demonstrated and experimentally validated in a series of beam tests, the use of standard Photo-Multiplier (PM) tubes to read out the *S* and *C* light has so far limited its development towards a full-scale system compliant with the integration in a particle detector at a colliding beam machine. These limitations should be overcome using SiPM, low-cost solid-state sensors of light with single photon sensitivity, magnetic field insensitivity and design flexibility.

As it will be shown in the following, the high readout granularity in the plane perpendicular to the shower development and few other signal properties will probably make redundant or even inessential the need of a longitudinal segmentation into *em* and hadronic compartments (that is anyway possible). In case of a segmented calorimeter, both compartments need to provide dual-readout signals, in order to allow for the measurement of $\langle f_{em} \rangle$.

5.5.2 Principle of dual-readout calorimetry

The independent sampling of hadronic showers, through scintillation and Čerenkov light emission, allows one to fully reconstruct, at the same time, energy and f_{em} of hadronic showers. In fact, the total detected signals, measured with respect to the electromagnetic energy scale, can be expressed as:

$$S = E [f_{em} + \eta_S \cdot (1 - f_{em})] \quad (5.5)$$

$$C = E [f_{em} + \eta_C \cdot (1 - f_{em})] \quad (5.6)$$

where $\eta_S = (h/e)_S$ is the ratio of the average S response for the non- em component to the em component in hadronic showers. The response being defined as the average signal per unit of deposited particle energy. $\eta_C = (h/e)_C$ is the same for the C signal. In a typical dual-readout calorimeter, $\eta_S \approx 0.7$ and $\eta_C \approx 0.2$. These two equations are easily solved giving:

$$\frac{C}{S} = \frac{[f_{em} + \eta_C \cdot (1 - f_{em})]}{[f_{em} + \eta_S \cdot (1 - f_{em})]} \quad (5.7)$$

$$E = \frac{S - \chi C}{1 - \chi} \quad (5.8)$$

where:

$$\chi = \frac{1 - \eta_S}{1 - \eta_C} = \cot \theta \quad (5.9)$$

This is the simplest formulation of hadronic calorimeter response: an em part with relative response of unity, and a $non-em$ part with relative response η .

There are two unknowns for each shower, E and f_{em} , and two measurements S and C . The electromagnetic fraction, f_{em} , is determined entirely by the ratio C/S , and the shower energy calculated as in Eq. 5.8. Both, S and C , $\eta = (h/e)$ ratios have event-by-event fluctuations and should be considered stochastic variables, nevertheless the average $\langle h/e \rangle$ values are essentially independent of hadron energy and species [24–26]. The global parameter χ can be extracted with a fit to calibration data:

$$\chi = \frac{E_0 - S}{E_0 - C} \quad (5.10)$$

$$S = (1 - \chi)E_0 + \chi C \quad (5.11)$$

where E_0 is the beam energy.

The geometrical meaning of the θ angle in Eq. 5.9 can be understood by looking at the scatter plot of C versus S signals in Figure 5.28. An illustration of the prediction for the scatter plot for protons and pions is shown in Fig. 5.28(a) and the scatter plot for 60 GeV pions measured in the RD52 lead-fibre calorimeter is shown in Fig. 5.28(b).

The plot in Figure 5.28(b) shows that the data points are located on a locus, clustered around a line that intersects the $C/S = 1$ line at the beam energy of 60 GeV. In first approximation, the signal generated in the Čerenkov fibres is produced only by the em components of the hadron showers. The smaller the em fraction f_{em} , the smaller the C/S signal ratio.

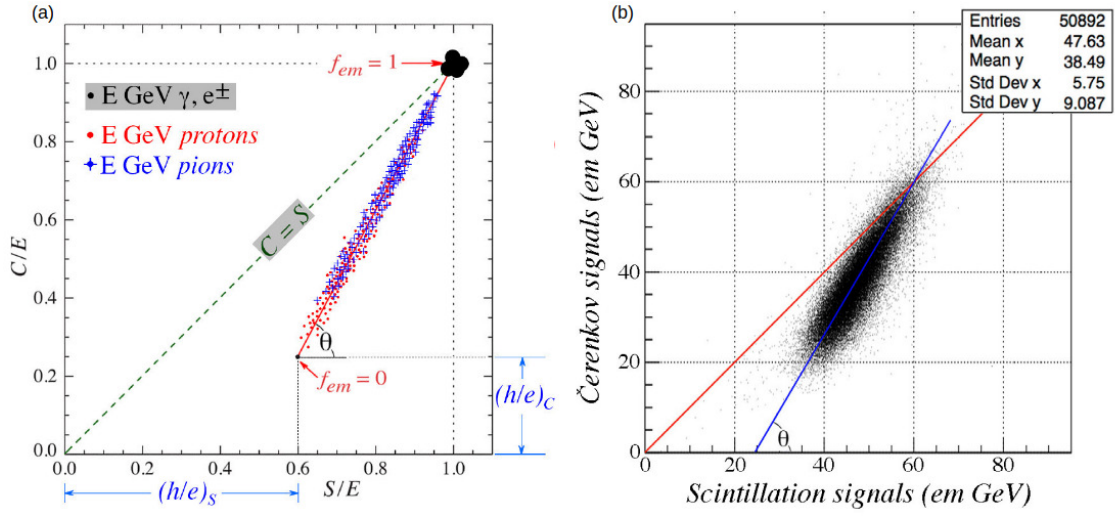

Figure 5.28: (a) Scatter plot of C/E versus S/E in a dual-readout calorimeter for p and π ; (b) scatter plot of C and S signals for 60 GeV pions in the RD52 lead-fibre calorimeter.

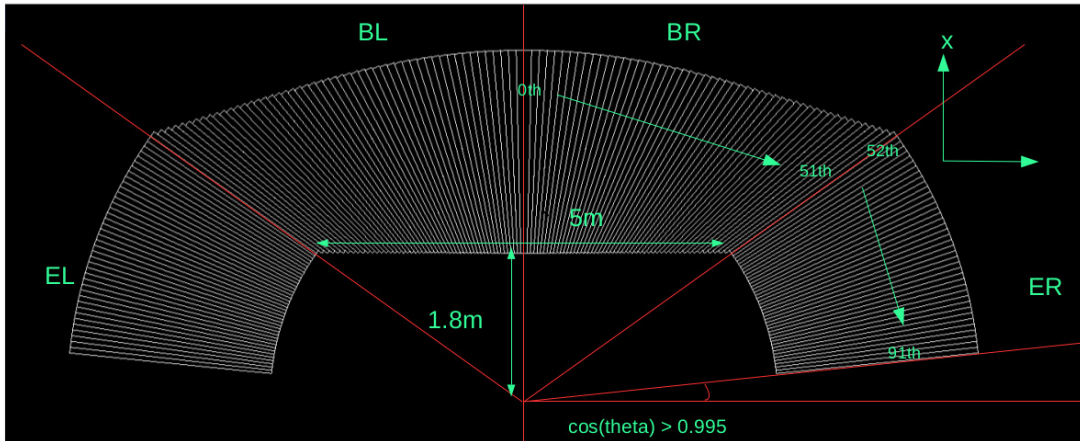

Figure 5.29: A possible 4π solution (called "wedge" geometry).

All signals are relative to the em scale meaning that both the Čerenkov and the scintillation responses are calibrated with beam electrons only, i.e. no hadronic calibration is required. This is one of the most qualifying and important points of dual-readout calorimetry.

The effectiveness of this approach has been demonstrated by the DREAM/RD52 collaboration over a 15-year research program with a variety of detector solutions. Results and simulations [27–32] provide, so far, confidence that a fibre-sampling calorimeter, even without longitudinal segmentation, may meet the requirements of the CepC physics programme in a cost-effective way. Linearity and energy resolution, for both em and hadronic showers, $e/\pi/\mu$ separation, spatial resolution, all show adequate performance.

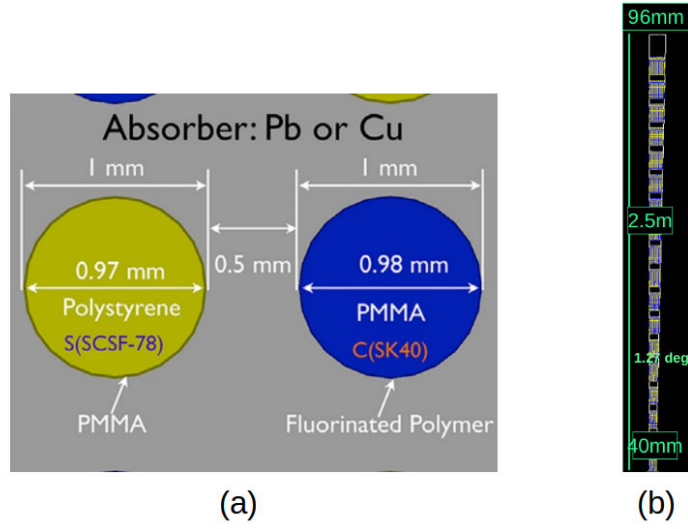

Figure 5.30: (a) Fibre arrangement inside the modules. (b) Dimensions of a module in the barrel region (at $\eta = 0$): from inside to outside the number of fibres more than doubles.

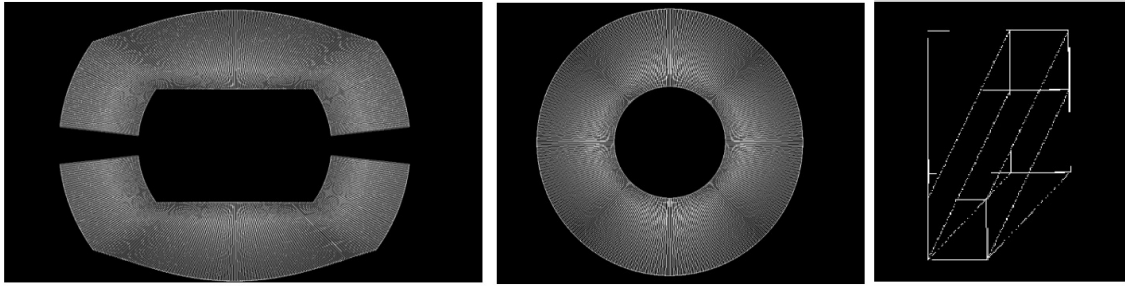

Figure 5.31: An alternative 4π solution (called "wing" geometry).

5.5.3 Layout and mechanics

5.5.3.1 Layout

A possible projective layout ("wedge" geometry, Figure 5.29) has been implemented in the simulations. Based on the work done for the 4th Detector Collaboration (described in its Letter of Intent [33]), it covers, with no cracks, the full volume up to $|\cos(\theta)| = 0.995$, with 92 different types of towers (wedges). A typical one in the barrel region is shown in Figure 5.30(b), together with the fibre arrangement (Figure 5.30(a)): it has an acceptance of $\Delta\theta \times \Delta\phi = 1.27^\circ \times 1.27^\circ$, a depth of about 250 cm ($\sim 10 \lambda_{\text{Int}}$), and contains a total of about 4000 fibres.

The sampling fraction is kept constant by fibres starting at different depths inside each tower. This layout has been already imported in the simulations for the CepC detector. Preliminary results on performance are shown in the next chapters.

A different layout implementing the "wing" geometry (see Figure 5.31) is also under study and preliminary results on the *em* performance will also be shown in the next chapters. In this case, the calorimeter is made of rectangular towers coupled with triangular ones.

In both cases, the total number of fibres is of the order of 10^8 for a complete 4π calorimeter.

Absorber Material	ρ (g/cm ³)	X_0 (cm)	$R_{\text{Molière}}$ (cm)	λ_{Int} (cm)	$\rho \times \lambda_{\text{Int}}^3$ (kg)
Copper (Cu)	8.96	1.44	1.57	15.3	32.2
Brass (Cu260)	8.53	1.49	1.64	16.4	37.8
Lead (Pb)	11.35	0.56	1.60	17.6	61.8
Iron (Fe)	7.874	1.76	1.72	16.8	37.1
Fibres:Copper (38:62)	5.98	2.26	2.28	21.9	62.8
Fibres:Brass (38:62)	5.72	2.35	2.38	23.3	72.1
Fibres:Lead (38:62)	7.46	0.90	2.33	24.7	112.8
Fibres:Iron (38:62)	5.31	2.75	2.48	23.7	70.8

Table 5.1: Main properties of lead, copper, brass and iron absorber material and of fibre sampling matrices (RD52 lead-fibre prototype geometry).

5.5.3.2 Mechanics (material choice and machining)

Copper, lead and brass (Cu260) have been used as absorber materials by the DREAM/RD52 collaboration. Their main properties are shown in the Table 5.1, that also reports the calculation for the RD52 lead-prototype geometry. The values for iron are also shown, for comparison. From the table it can be seen that, for hadronic showers, a full-coverage solution with lead (Pb) will give 6% broader and longer showers and a total mass 56% heavier than using brass. A full-containment $3 \times 3 \times 10 \lambda^3$ prototype will need ~ 5 tons of material with lead (Pb) and ~ 3.2 tons with brass (Cu260).

A possibly stronger reason in favour of copper/brass is the fact that, since the e/mip ratio is 50% higher for copper than for lead, the Čerenkov light (almost exclusively produced by the em component of the shower) has a larger yield for copper, resulting in a better hadronic resolution [23]. However this statement needs to be quantified since it depends on the absolute level of the Čerenkov light yield(s).

On the other hand, lead is easily and accurately extruded, whereas forming copper into the desired shape, either by extrusion, molding, or machining, with the required tolerances in planarity and groove parallelism, is not yet an established industrial process. A variety of techniques (extrusion, rolling, scraping, and milling) for forming the converter layers have been tested. None has been qualified for a large-scale production and identifying an industrial and cost-effective process, including moulding, is a key point.

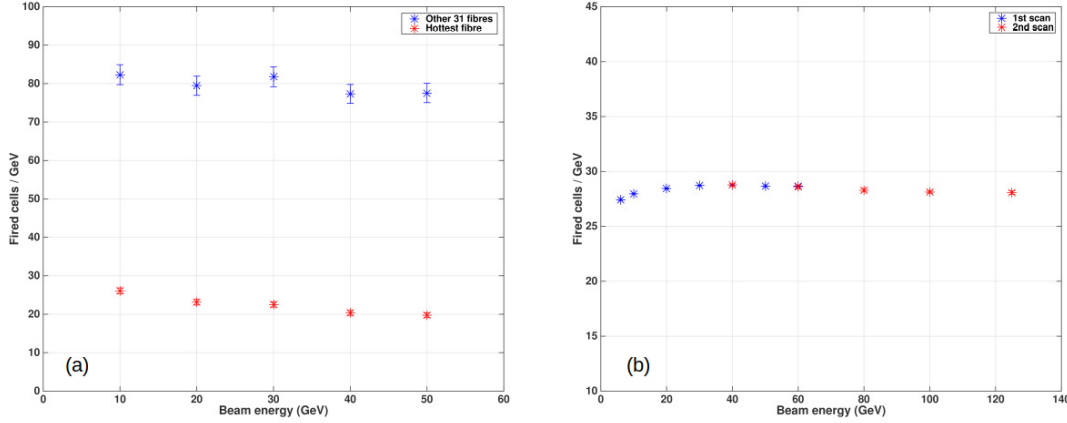

Figure 5.32: Number of photoelectrons per GeV (pe/GeV) for (a) S and (b) C signals, as a function of the electron energy, from 10 to 50 GeV, in a small 64-fibre brass module. In (a), the results are shown separately for the hottest fibre and for the sum of the signals measured by the other 31 scintillating fibres obtained at the (ultra low) PDE of $\sim 2\%$. The main sensor specifications were: 1600 , $25 \times 25 \mu m^2$, cells, and a 25% nominal PDE.

Alternative copper alloys (e.g. bronze) and/or materials (e.g. iron) may be investigated as well, both for addressing the production process issues and for optimising the detector performance.

5.5.4 Sensors and readout electronics

To separately read out the signals from the S and C fibre forest and avoid oversampling of late developing showers is an issue that may be successfully addressed through the use of Silicon Photo-Multipliers (SiPM). They would allow the separate reading of each fibre and provide magnetic field insensitivity. In principle, assuming powering and cooling do not pose issues, the transverse segmentation could be made as small as a fibre spacing, or 1.5 mm .

SiPMs are low-cost solid state light sensors with single photon sensitivity that underwent an impressive development over the last few years. Tests done in the last two years by the RD52 collaboration indicate that effective solutions for small-scale prototypes are very close already now. Thanks to their higher photon detection efficiency with respect to a standard PM, the higher number of Čerenkov (pe) should result in an improved resolution for both em and hadronic showers. On the other hand, the scintillation light spans a very large dynamic range and saturation and non-linearity effects were observed already for low-energy em showers.

In Figure 5.32, the number of photoelectrons per GeV (pe/GeV) measured, in July 2017, with a very small module ($\sim 1 \text{ cm}^2$ cross section, $32 + 32$ fibres), is shown. The most relevant sensor characteristics are 1600 , $25 \times 25 \mu m^2$, cells, and a 25% nominal PDE. Due to the large S light yield, the data for the S signal were obtained at an (ultra low) PDE of $\sim 2\%$, and corrected for non-linearity. Rescaled to a 25% efficiency, the yield of S photoelectrons results in $\sim 108 \times 12.5 = 1350 \text{ } pe/GeV$. By removing from the sum the hottest fibre, more heavily affected by non-linearity effects, the estimate grows to $\sim 1530 \text{ } pe/GeV$.

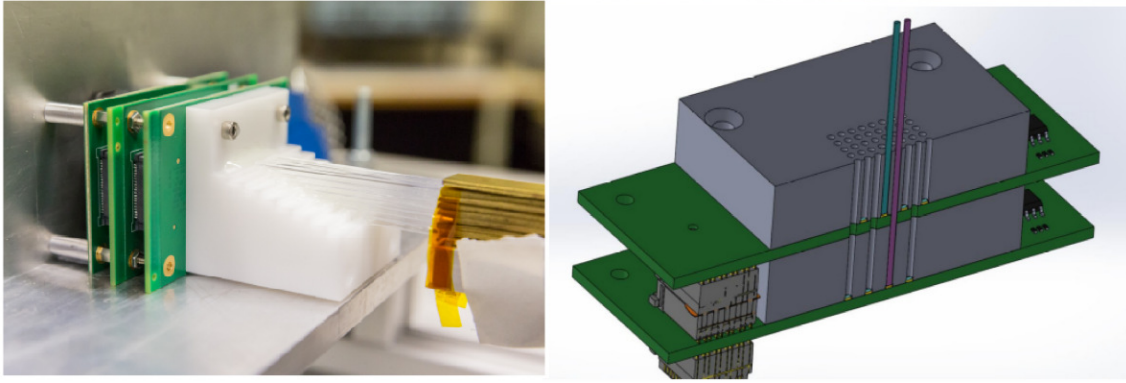

Figure 5.33: Staggered readout scheme: the scintillation and Čerenkov fibres are readout at different planes to minimise light leakage into neighbouring channels.

The C signals show a linear response at $\sim 30 \text{ pe/GeV}$. It should be mentioned that the shower containment was estimated from GEANT4 simulations to be $\sim 45\%$. In addition, the problem of large light leaks from the S fibres into the neighbouring C SiPM channels, observed in the 2016 tests, seems to be largely but not completely solved by a staggered readout of the S and C fibres (Figure 5.33). The contamination of the C signal was estimated to be $\sim 16\% \pm 6\%$.

5.5.4.1 Sensor choice

As far as the scintillation light detection is concerned, saturation and non-linearity should be solvable using higher density devices (e.g. with 10000, $10 \times 10 \mu\text{m}^2$, cells) in combination with some light filtering. The definition of the optimal dynamic range and the qualification of existing SiPMs in that regard, will be likely addressed in a short-term R&D phase.

For the Čerenkov light, improvements of the photon collection are possible with the use of an aluminised mirror on the upstream end of the fibres. The acceptance cone may also be enlarged with the use of cladding with a different refractive index. Over a longer term, it could be possible that the R&D on new devices, such as Silicon Carbide (SiC) sensors, expected to provide exclusive UV sensitivity (i.e. visible-light blindness), will allow us to obtain significantly larger pe yields.

5.5.4.2 Front-end electronics and readout

Concerning the front-end, the development shall certainly evaluate the use of Application Specific Integrated Circuits (ASIC) to handle and reduce the information to be transferred to the DAQ system. A major question is finding the optimal way for summing signals from a plurality of sensors into a single output channel. A dedicated feature-extracting processor, capable of extracting timing information such as time-over-threshold, peaking, leading and/or falling times, may allow to disentangle overlapping em and hadronic showers without the need for longitudinal segmentation. With the present fibres, a resolution of the order of 100 ps corresponds to a spatial resolution of about $\sim 6 \text{ cm}$ along the fibre axis (relativistic particles take 200 ps to cover 6 cm while light needs 300 ps).

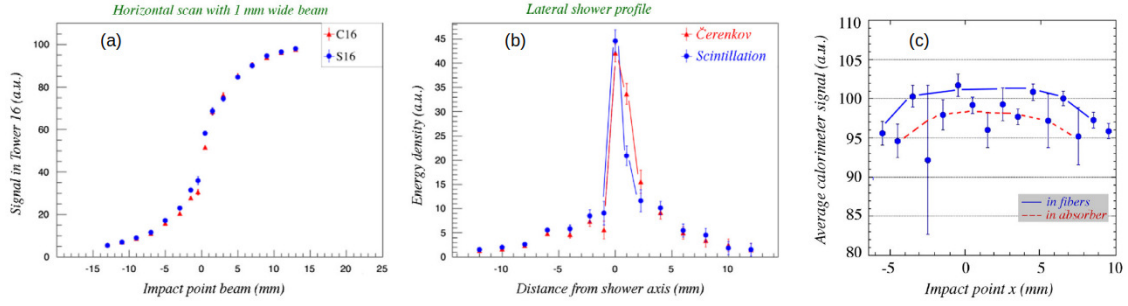

Figure 5.34: (a) The signal from a 1 mm wide beam of 100 GeV electrons, in the RD52 lead-fibre prototype, as a function of the impact point; (b) the lateral shower profiles derived from this measurement; (c) the dependence of the scintillation signal on impact point for a beam impinging parallel to the fibres.

5.5.5 Performance studies with fibre-sampling prototypes

Different prototypes were built and studied by the DREAM/RD52 collaboration, with copper or lead as absorber and photomultipliers as light sensors [27–32]. With electrons and pions, in the range of ~ 10 -150 GeV, the response linearity was found at the level of 1% for both the *em* and the hadronic energy reconstruction (having applied the dual-readout formula, equation 5.8, for hadronic showers). The *em* resolution was estimated to be close to $\sim 10\%/\sqrt{E}$, while the hadronic resolution was found to be at the level of 60 - $70\%/\sqrt{E}$, to be corrected for the fluctuations introduced by lateral leakage and light attenuation in the fibres. None of the prototype was large enough to substantially contain hadronic showers and an R&D programme to assess the hadronic performance of a real detector, is under way. Preliminary simulations of standalone modules indicate a possible ultimate resolution of ~ 30 – $40\%/\sqrt{E}$. More details can be found in the next paragraphs.

5.5.5.1 Electromagnetic performance

Figure 5.34(a) and 5.34(b) show the radial shower profile and the sensitivity to the impact point: the core of the signal spans just a few mm. Figure 5.34(c) shows the dependence of the *S* signal on the impact point for particles entering parallel to the fibres. This introduces a constant term in the resolution that can be avoided with a small tilt of the fibre axis. In the *C* fibres, the problem does not show up since the early (collimated) part of the shower produces photons outside the fibre numerical aperture.

For the reconstruction of the energy of *em* showers, *S* and *C* signals provide independent uncorrelated measurements, with different sensitivity of the response. They are affected by different problems: *S* signals have photoelectron statistics one or two orders of magnitude higher than *C* signals, and their fluctuations are largely dominated by the sampling fluctuation of the energy deposits. *C* signal fluctuations are generally dominated by the limited photoelectron statistics, especially at low energies. Nevertheless, at high energies, the constant term for *C* signals is negligible, giving a better resolution. Averaging the two measurements improves the resolution up to a factor of $\sqrt{2}$. For the copper matrix, in Figure 5.35(a) the sum of *S* and *C* signals for 40 GeV electrons is plotted, while Figure 5.35(b) shows the *em* resolution, for *S*, *C* and the (average) combined signal.

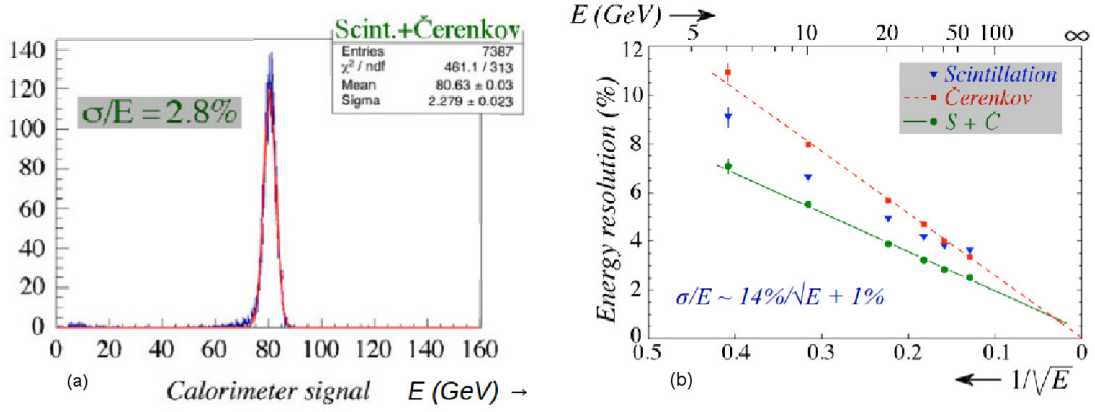

Figure 5.35: In the RD52 copper-fibre module: (a) signal distribution of the sum of all fibres for 40 GeV electrons; (b) the em energy resolution as a function of the beam energy. Shown are the results for the two types of fibres, and for the average combined signal.

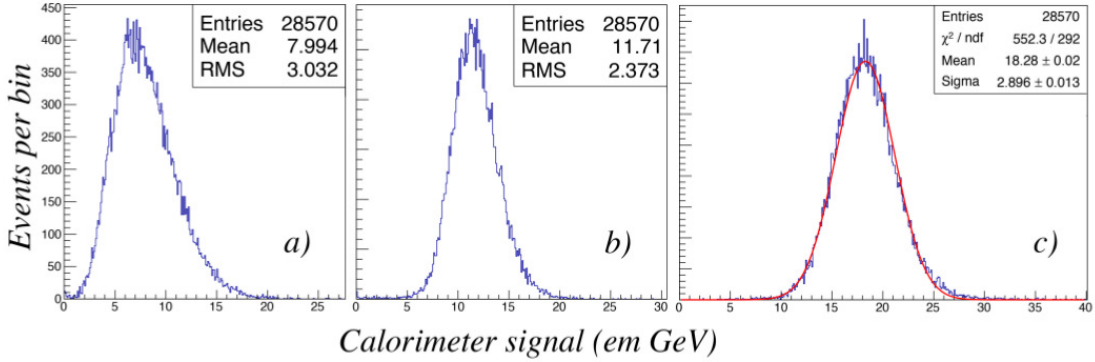

Figure 5.36: Signal distributions for 20 GeV π^- particles in the RD52 lead-fibre matrix. Shown are the measured (a) Čerenkov and (b) scintillation signal distributions as well as (c) the distribution obtained by combining the two signals according to Equation 5.8, with $\chi = 0.45$.

5.5.5.2 Hadronic performance

The response of a lead-fibre matrix was studied with pion and proton beams [32]. The energy was reconstructed with the dual-readout relation (Eq. 5.8) and shows a restored gaussian response function (Figure 5.36) and linearity of the mean response.

The comparison of p and π^+ signals confirms that the dual-readout method largely compensates for the differences in shower composition, i.e., differences in the electromagnetic fraction, f_{em} , and between baryon-initiated and pion-initiated hadronic showers.

Due to the limited lateral size of the matrix (the effective diameter was $\sim 1\lambda_{Int}$), the containment for hadronic showers was $\sim 90\%$ so that leakage fluctuations dominated the energy resolution. Selecting contained showers improved the resolution by a factor of ~ 2 . Although that selection was introducing a bias in favour of high f_{em} showers, a significant improvement is expected for a realistic-size module.

The resolution was also affected by the finite light attenuation length of the fibres, causing early starting showers to be observed at lower signal values. The hadronic resolution, yet to be corrected for both effects, was reconstructed to be $\sim 70\%/\sqrt{E}$.

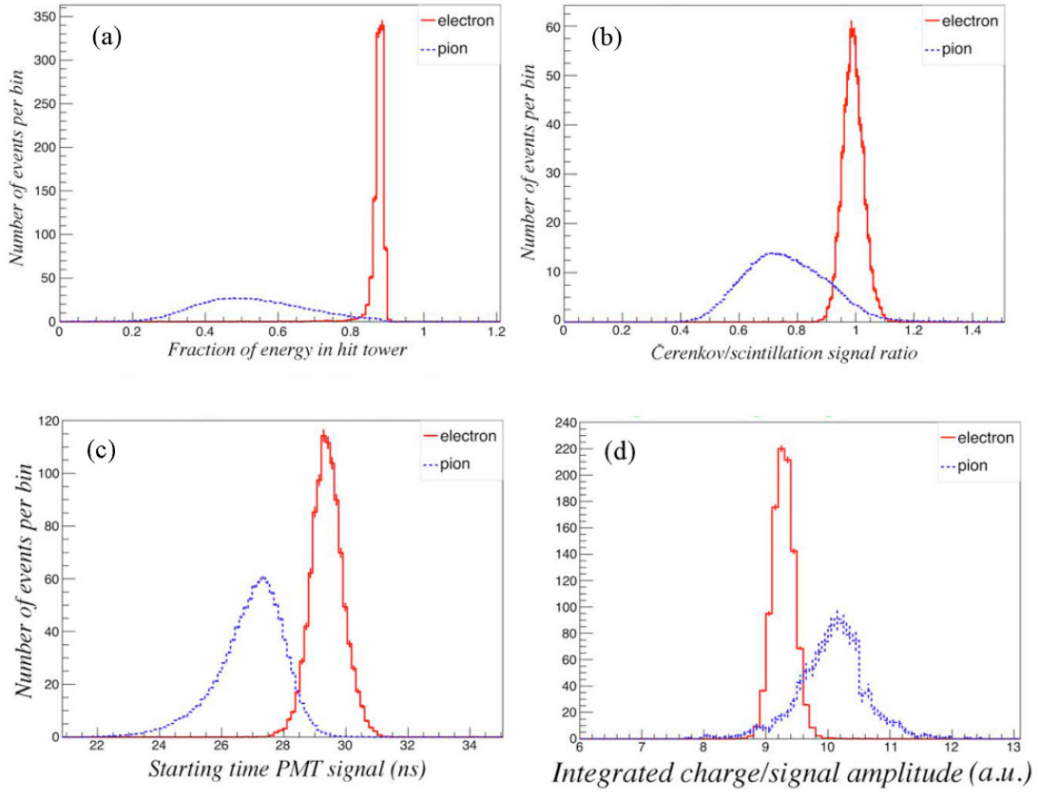

Figure 5.37: Distribution of four discriminating variables for 60 or 80 GeV electrons and pions, as measured with the RD52 lead-fibre prototype: (a) energy fraction deposited in the hit tower; (b) C/S signal ratio in the hit tower; (c) starting time of the PM signal; (d) ratio of the integrated charge and the amplitude of the signals.

5.5.5.3 e/π separation

Four discriminating variables were identified for implementing e/π separation: the fraction of energy in the central tower, the C/S signal ratio, the signal starting time and the total charge/amplitude ratio, shown in Figure 5.37. The plots are relative to testbeam data taken with the RD52 lead-fibre prototype [27].

A multivariate neural network analysis showed that the best e/π separation achievable for 60 GeV beams was 99.8% electron identification efficiency with 0.2% pion misidentification. Further improvements may be expected by including the full time structure information of the pulses, especially if the upstream ends of the fibres are made reflective.

5.5.6 Montecarlo simulations

GEANT4 simulations ¹ are under development and analysis for understanding the performance of both testbeam modules and a 4π calorimeter integrated in a detector, with magnetic field, tracking and preshower elements.

¹version 10.02.p01-10.03.p01, with FTFP_BERT_HP physics list

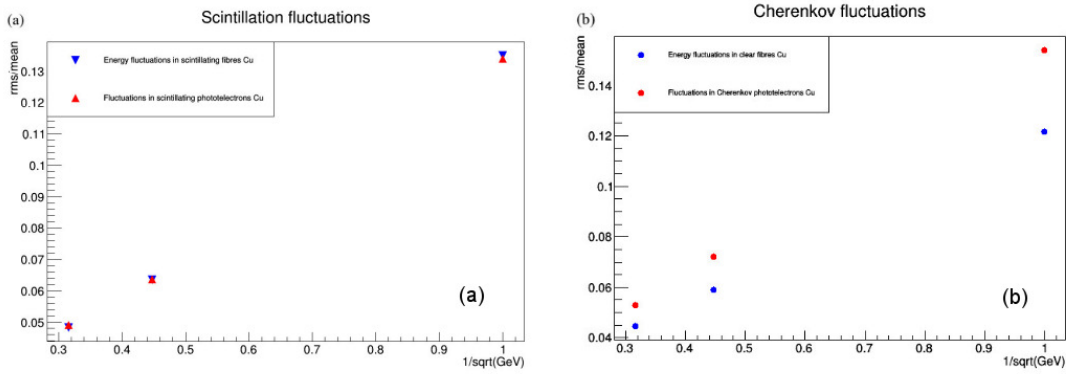

Figure 5.38: Relative fluctuation of the total signal detected in the (a) scintillating and (b) Čerenkov fibres, for both the energy deposit and the number of photoelectrons (MC simulations).

5.5.6.1 *em* performance

A Cu matrix of dimensions $\sim 31 \times 31 \times 100 \text{ cm}^3$, with 1 mm fibres at 1.4 mm distance, compatible with the RD52 prototypes, has been simulated for the evaluation of the electromagnetic performance. PMMA clear fibres and Polystyrene scintillating fibres, with a 3% thick cladding (C_2F_2 Fluorinated Polymer for clear and PMMA for scintillating fibres), were the sensitive elements.

A small ($\lesssim 1^\circ$) tilt angle was introduced to avoid large non-Gaussian tails in the scintillation signal due to channeling.

The energy containment for 20 GeV electrons was estimated to be $\geq 99\%$, with sampling fractions of 5.3% and 6.0% for scintillating and clear fibres, respectively.

Given the integral sampling fraction of 11.3% and the 1 mm diameter fibres, the contribution to the energy resolution due to sampling fluctuations can be estimated to be $\sim 9\%/\sqrt{E}$, ultimate limit on the *em* resolution for this detector.

The scintillation light yield is so large ($\sim 5500 \text{ pe/GeV}$) that the fluctuations of the *S* signals are dominated by the energy sampling process (Figure 5.38(a)). This is not true for the Čerenkov signals (Figure 5.38(b)), whose sensitivity is estimated to be $\sim 100 \text{ pe/GeV}$.

So, in the simulations, the process of generation and propagation of the scintillation light was switched off and the energy deposited in the fibres was taken as signal since this does not introduce any bias to the detector performance. This statement does not apply to the Čerenkov photons for which a parameterization that convolutes the effect of light attenuation, angular acceptance and PDE, was introduced.

In Figure 5.39 the resolutions are shown for both *C* and *S* signals, separately, and for the unweighted average value of the two. The variable on the horizontal axis and in the formulae for the fitted resolutions is the beam energy. The results of the fit to the data points are shown in Table 5.2. A slightly better result may be obtained with a weighted average.

5.5.6.2 Hadronic performance

A simulation of larger ($\sim 72 \times 72 \times 250 \text{ cm}^3$) matrices was implemented in order to get a hadronic shower containment of $\sim 99\%$. Calibration was done with 40 GeV electron beams.

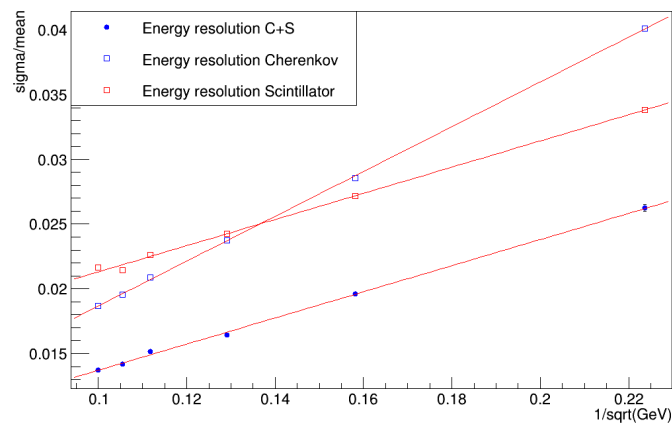

Figure 5.39: Relative resolution for em showers for the C and S signals, independently, and for the average of the two (MC simulations).

Fibers used	Fitted Gaussian electromagnetic energy resolution
S-fibres only	$\sigma/E = 10.1\%/\sqrt{E} \oplus 1.1\%$
C-fibres only	$\sigma/E = 17.3\%/\sqrt{E} \oplus 0.1\%$
S-fibres and C-fibres	$\sigma/E = 10.1\%/\sqrt{E} \oplus 0.4\%$

Table 5.2: Fit to the em resolution (MC simulations)

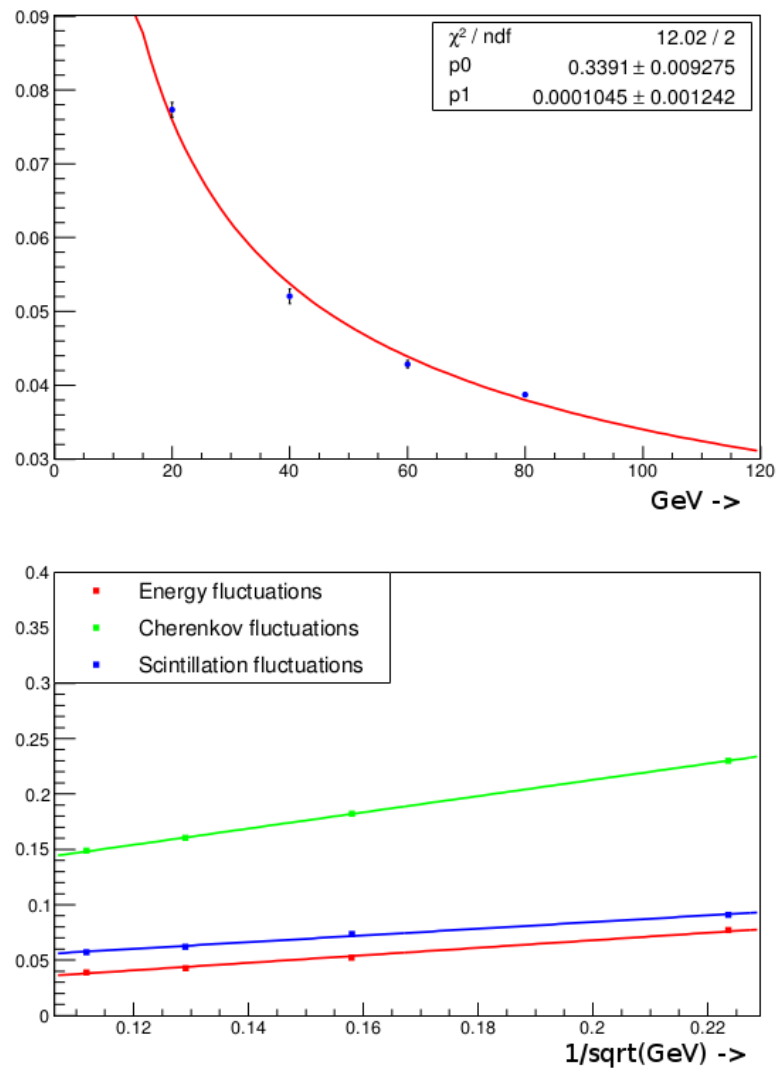

Figure 5.40: Montecarlo simulations showing: (top) the relative hadronic resolution as reconstructed with the dual-readout formula; (bottom) the relative hadronic resolution independently for the C and S signals and for the dual-readout combination of the two.

Fiber used	Fitted Gaussian hadronic energy resolution
S-fibres only	$\sigma/E = 30\%/\sqrt{E} \oplus 2.4\%$
C-fibres only	$\sigma/E = 73\%/\sqrt{E} \oplus 6.6\%$
Dual-readout S-fibres and C-fibres	$\sigma/E = 34\%/\sqrt{E} \oplus (\text{negligible})\%$

Table 5.3: Fit to the hadronic resolution (MC simulations)

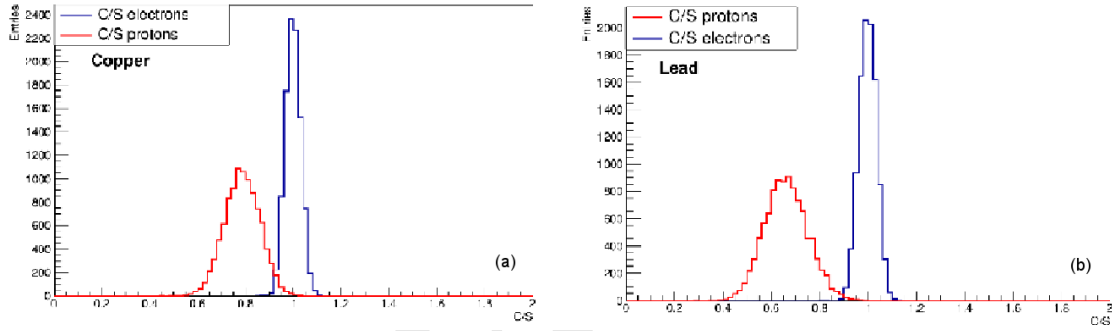

Figure 5.41: C/S ratio (MC simulations) for 80 GeV e^- and protons in (a) copper and (b) lead.

In Figure 5.40 GEANT4 predictions for the hadronic energy resolution, with copper absorber, are shown. Table 5.3 lists the results of the fit to the curves.

The large constant terms, for both S and C signals, are generated by the f_{em} correlated fluctuations. Simulations with lead absorber give equivalent but even slightly better results. The energy E in the plot (and in the expressions for the fitted resolutions) is the beam energy, corresponding in average to the energy reconstructed with the Equation 5.8 when the containment is properly accounted for (i.e., the reconstructed energy corresponds, in average, to the beam energy times the average containment). The fact that the experimental resolution was, so far, about a factor of two worse than simulations, is in our understanding, largely due to the small lateral size of the prototypes. In order to fully validate the MC predictions, an R&D programme is being pursued.

The correlation of the invisible energy with all the other components of hadronic showers was also analysed. Preliminary results seem to indicate that the most appropriate variable to account for the fluctuations of the invisible energy component is, by far, the f_{em} , with correlation coefficients of 90%, 92%, 94%, for copper, iron and lead respectively. The kinetic energy of the neutrons is predicted to be, at best, correlated at the 76% level. If confirmed, this would prove that compensation through neutron signal pickup or amplification will anyway give worse results than the dual-readout method [34].

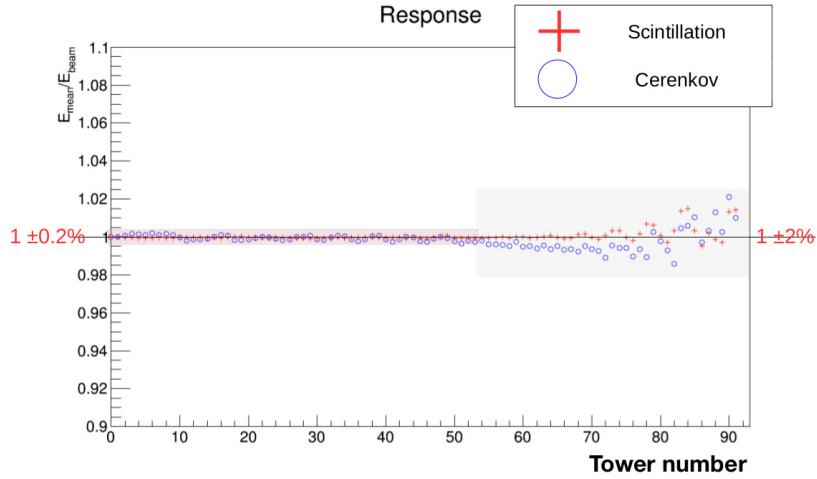

Figure 5.42: Ratio of reconstructed energy to the beam energy for 20 GeV e^- , as a function of the tower number, in the wedge geometry (MC simulations).

About particle ID capabilities, in Figure 5.41 the C/S ratio is shown for 80 GeV e^- and protons in copper (left) and lead (right). For an electron efficiency of $\sim 98\%$, the rejection factor for protons is ~ 50 in copper and ~ 600 in lead. Of course, this is an ideal detector and in reality it is likely that the numbers will be worse. On the other hand, there are more variables that can be easily used in order to enhance the particle ID performance (namely the lateral shower profile, the starting time of the signal, the charge-to-amplitude ratio).

5.5.6.3 Projective geometry

Each tower, in the wedge geometry implementation, was exposed to 20 GeV electron beams, with an incident angle of (1° , 1.5°), and the calibration constants calculated as the average deposit energy (in each tower) divided by the average C or S signal (of each tower). The response to an electron beam of the same energy is plotted in Figure 5.42. In the barrel region the response of all towers is within 0.2%, while in the forward the systematics are within 2%. All results were obtained with the quantum efficiency for the Čerenkov channel of each tower tuned to a light yield of ~ 30 pe/GeV , as estimated in the RD52 beam tests.

The performance of a few towers was studied with electron beams in the range of 10-100 GeV. Figure 5.43 shows the linearity and em energy resolutions for towers #0 and #45. In both cases, the combined S and C signal shows a resolution of $\sim 14\%/\sqrt{E}$ with a constant term of $\sim 0.1\%$ while the average response is constant within 0.4%.

The hadronic resolution was studied with pions in the same energy range. A χ value of 0.29, the value measured for the DREAM calorimeter [35], was used to reconstruct the shower energy with Eq. 5.8. In the linearity plots for both tower #0 and #45 in Figure 5.44(a), the C and S responses to single pions increase non-linearly as the pion beam energy increases. On the other hand, the value reconstructed with the dual-readout formula shows a constant response to single pions $\sim 8\%$ lower than that to electrons (the reason being the shower containment). This effect in the GEANT4 simulations is described in reference [36]. In addition, the energy resolution after the correction (shown in Figure 5.44(b) for towers #0 and #45) is $\sim 26\%/\sqrt{E}$, with a constant term of less than

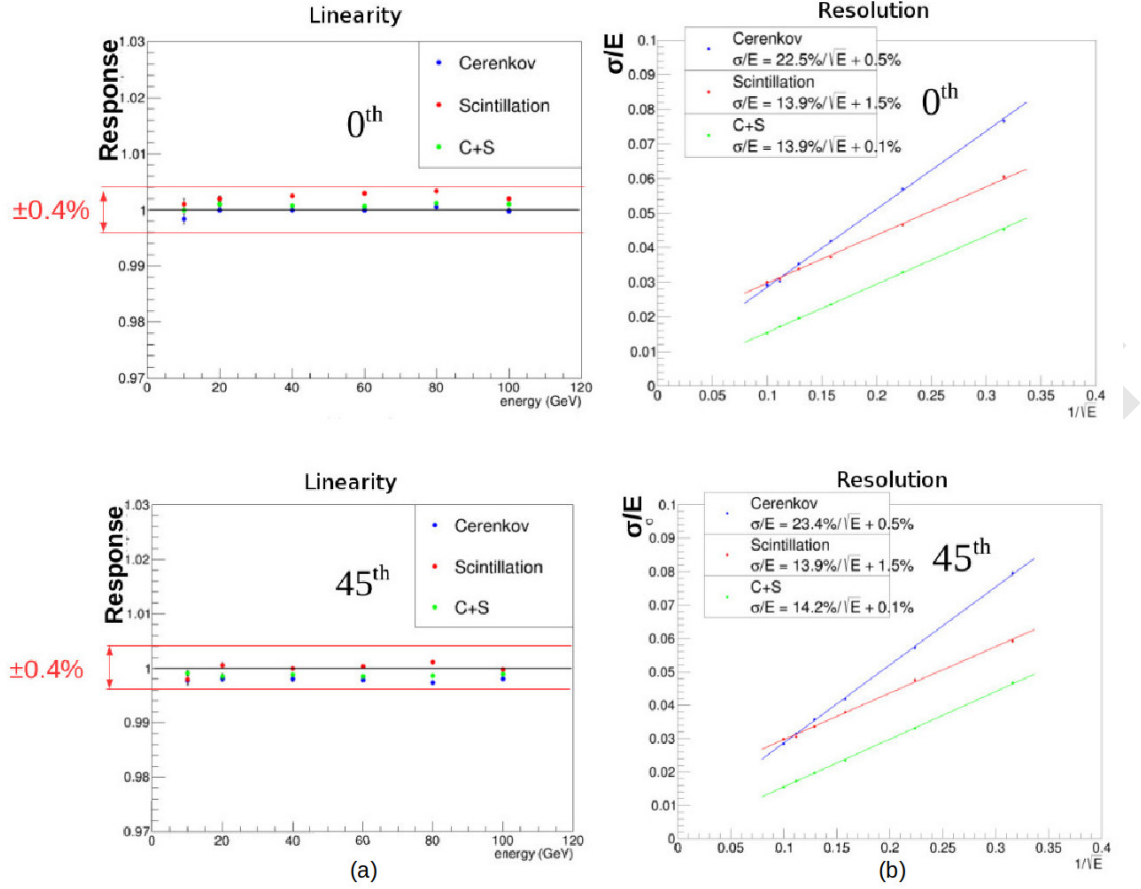

Figure 5.43: Linearity and em energy resolution for towers #0 (top) and #45 (bottom), in the wedge geometry (MC simulations).

1%. These results support the statement that the hadronic energy resolution and the response to single hadrons should be constant (and appropriate) over the full barrel region. We may reasonably expect to obtain good performance over the entire 4π detector.

For the wing geometry, the results, at present, are limited to the em performance of few towers and the results (linearity and em resolution) substantially reproduce the wedge geometry ones.

5.5.6.4 Short term planning and open issues

The performance for single hadrons, jets and τ leptons has to be understood and the work has just started. For validation, the comparison with a prototype with a non-marginal hadronic shower containment, like the RD52 lead matrix, will be pursued.

About em simulations, a program for the comparison with the 2017 RD52 data is ongoing. Some initial understanding of the absolute photoelectron scale for the Čerenkov light should be available in a very short time.

In general, light attenuation effects need also to be considered, for a $\sim 2 - 2.5m$ long fibre detector, that may introduce a constant term in the hadronic resolution as a function of the shower development point (late starting showers will give bigger and earlier signals).

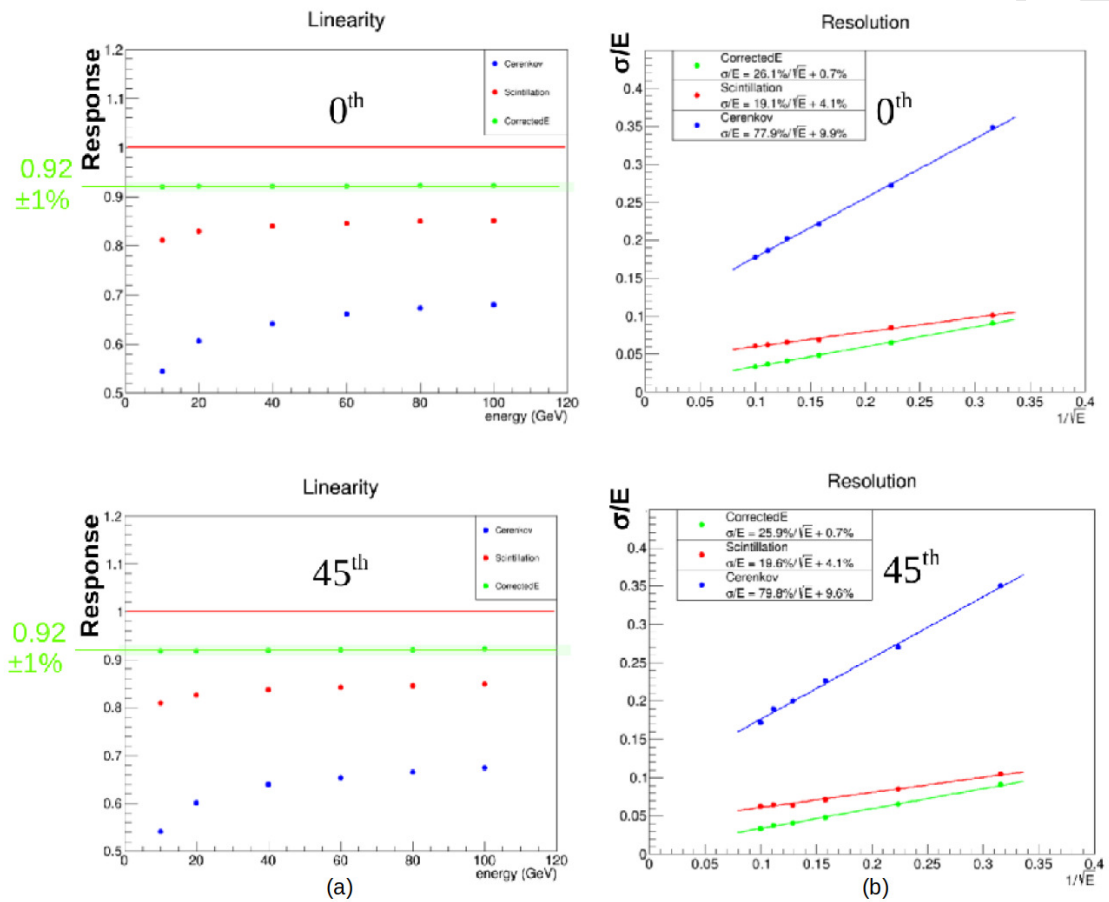

Figure 5.44: Linearity and energy resolution with pions, for towers #0 (top) and #45 (bottom), in the wedge geometry (MC simulations).

The evaluation of advantages and disadvantages of filters (to dump the short attenuation-length components) and mirrors (to increase the number of photons that reach the photodetectors) may be relevant in this context.

The effects of the integration of a preshower detector have to be evaluated and the e/π separation capability assessed and quantified, for both isolated particles and particles within jets.

About physics, a (non exhaustive) list of benchmark channels to be studied is:

$$H \rightarrow \gamma\gamma$$

$$H \rightarrow \tau\tau \rightarrow e/\mu + \rho\pi$$

$$H \rightarrow gg \rightarrow jj$$

$$Z \rightarrow jj$$

$$W \rightarrow jj$$

$$H \rightarrow ZZ^* \rightarrow 4j$$

$$H \rightarrow WW^* \rightarrow 4j.$$

5.5.7 Final remarks

Thanks to a 15-year-long experimental research program on dual-readout calorimetry of the DREAM/RD52 collaboration, this technology looks mature for the application in future experimental programs. The results show that the parallel, independent, readout of scintillation and Čerenkov light, makes it possible to cancel the effects of the fluctuations of the electromagnetic fraction in hadronic showers, dominating the energy resolution of most (if not all) the calorimeters built so far. In conjunction with high-resolution em and hadronic energy measurements, excellent standalone particle-ID capability has been demonstrated as well.

Those results give increasing support to the conviction that a matrix of alternating scintillating and clear fibres, inserted in copper or lead strips and readout by Silicon PhotoMultipliers (SiPM), will be able to provide performance more than adequate for the physics programs at the proposed CepC collider.

Nevertheless, there is a series of technical and physics issues that need to be solved, within the next 2-3 years in order to arrive up to the design of a realistic 4π detector. A non-exhaustive list must include:

1. The industrial machining of foils of copper, lead or some other material, with the required precision.
2. The development of a mechanical integration design.
3. The readout of the high granularity matrices of SiPM that, in order to be effective, will require the development of a dedicated Application Specific Integrated Circuit (ASIC). Possible aggregations of more fibre outputs into a single channel have also to be implemented and studied.
4. The need and, in case, the way for a longitudinally segmented calorimeter system and the performance of Particle Flow Algorithms to further boost the performance of dual-readout.
5. The development of a modular solution and the assessment, at all levels, of its performance, through beam tests of small modules and simulations. An intensive program of simulations is already ongoing, targeted at the CepC experimental program. The

response to single particles and jets is under study, in standalone configurations. The work for understanding the behaviour of a 4π calorimeter integrated in a full detector, with a tracking and a magnetic system, has also started. This will include, as well, the evaluation of the combined performance with a preshower detector in front.

CHAPTER 6

DETECTOR MAGNET SYSTEM

The CEPC detector magnet is an iron-yoke-based solenoid to provide an axial magnetic field of 3 Tesla. A room temperature bore is required with a diameter of 6.8 m. This chapter describes the conceptual design of magnet, including the design of field distribution, solenoid coil, cryogenics, quench protection, power supply and the yoke. In the end of this chapter, the R&D section 6.5 brings up other concept options and some reach projects.

Compensation magnets are discussed in the Accelerator CDR chapter 9.2.

6.1 Magnetic field design

6.1.1 Main parameters

The CEPC detector magnet follows the same design concepts of the CMS and ILD detector magnets [1, 2]. The magnet system consists of the superconducting coil and the iron yoke with a barrel yoke and two end-cap yokes. The superconducting coil is designed with 5 modules wound with 4 layers. The three middle coil modules and the two end coil modules are wound with 78 and 44 turns, respectively. The operating current is 15,779 A for each turn corresponding to 3 T at the interaction point. The geometrical layout of magnet are shown in Figure 6.1. The main magnetic and geometrical design parameters are given in Table 6.1.

6.1.2 Magnetic field design

The magnetic field simulation has been calculated in 2D FEA model, with fine structure of the barrel yokes and end-cap yokes. Figure 6.2 shows the magnetic field contour of the

The solenoid central field (T)	3	Working current (kA)	15779
Maximum field on conductor (T)	3.485	Total ampere-turns of the solenoid (MA _t)	20.323

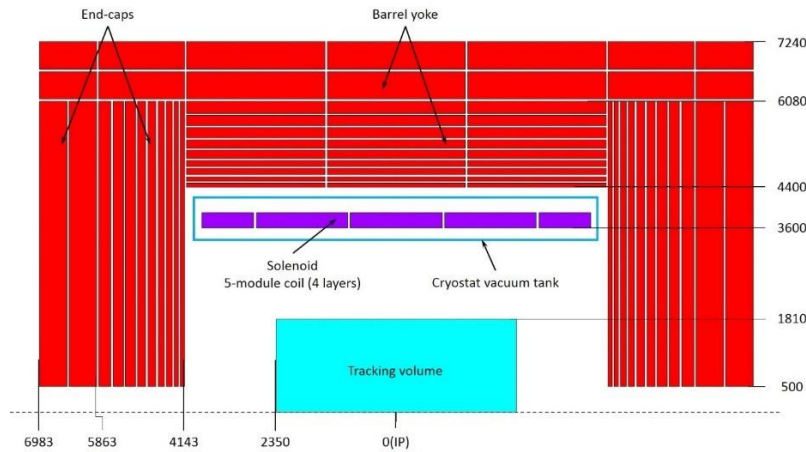

Figure 6.1: 2D layout of CEPC detector magnet (mm)

magnet. The maximum field on NbTi cable is 3.5 Tesla. The edge of 50 Gauss stray field is at 13.6 m from the beam axis and axial direction 15.8 m from the IP.

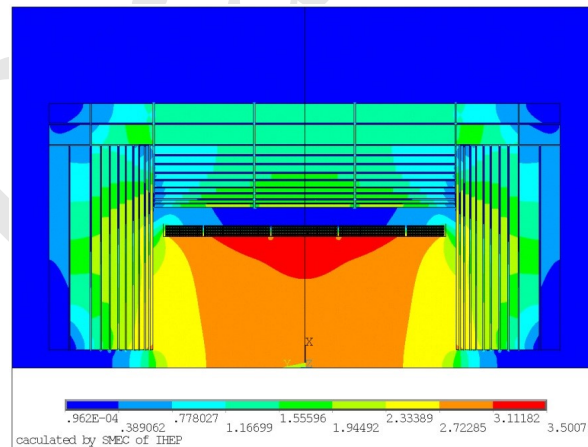

Figure 6.2: Field map of the magnet (T)

6.2 Solenoid Coil

The conceptual superconducting conductor is based on the self-supporting conductor design of CMS detector magnet, composed of NbTi Rutherford cable, the pure aluminum stabilizer and aluminum alloy reinforcement.

The coil windings is wound by inner winding technique with the support aluminum-alloy cylinder, which acts as an external supporting mandrel and taking away the quench induced heat energy. In order to maintain the operating temperature of LTS detector magnet, the cooling tubes for circular flow of LHe are welded on the outer surface of the aluminum-alloy cylinder.

6.3 Ancillaries (cryogenics, power supply, quench protection)

6.3.1 Cryogenics System

The coil cryogenic system is based on the CMS cryogenic system. The magnetic stored energy is 1.3 GJ. The thermosiphon principle is used for the coil indirect cooling mode using saturated liquid helium. A horizontal cryostat is designed, including a vacuum tank, an inner thermal shield, an outer thermal shield. The stainless steel vacuum vessel is 8.05 m length cylinder with diameter of 8.5 m. Two service towers are designed on the top of the cryostat in the central ring of the barrel yoke.

6.3.2 power supply

A low ripple DC current-stabilized power supply, with low output voltage and high output current, is requested for CEPC detector magnet. The power supply is expected to have a free-wheel diode system and to be cooled with demineralized water. The main circuit of a standard power supply includes 12 pulse diode rectifiers and 4 IGBT chopper units with a switching frequency of 10 kHz.

6.3.3 Quench Protection and Instrumentation

Selected voltage signals from the CEPC detector magnet coil and current leads are monitored by an FPGA board for quench detection. If a quench happened, the power supply is switched off and a dump resistor is switched into the electrical circuit, the huge stored energy will be extracted mainly by the dump resistor and partially by the coil itself. In order to monitor the status of the magnet, sensors or tools are added inside or outside to monitor temperature (busbar, current lead, valve box and etc), stress (tie rods), vacuum, coil current, liquid helium level, position (coil section) and etc.

6.4 Iron Yoke Design

The iron yoke is designed not only for field quality but also for resisting magnetic forces, as well as the mechanical support of the sub-detectors. Therefore high permeability material with high mechanical strength is required for the yoke material in account of mechanical performance and magnetic field. The yoke also provides room for the muon detector, which will sit between layers of the yoke, and allow space for data cables, cooling pipes, gas pipes and etc. through the yoke. The yoke is divided into two main components, one cylindrical barrel yoke and two end-cap yokes. The total weight of the yoke assembly is about 10,000 tons.

The barrel yoke is a dodecagonal shape structure with a length of 8,200 mm (Fig. 6.3). The outer diameter of the dodecagon and the inner diameter are 13,300 mm and 7,800 mm. The barrel yoke is subdivided along the beam axis into 3 rings, with 11 layers

in each ring. Each ring of the barrel yoke is composed of 12 segments. 40 mm gap is designed between the rings and the layers for placing the muon detector and the electronics cables and services. From the inner to the outer, the layer thicknesses are 80 mm, 80 mm, 120 mm, 120 mm, 160 mm, 160 mm, 200 mm, 200 mm, 240 mm, 540 mm, 540 mm, respectively.

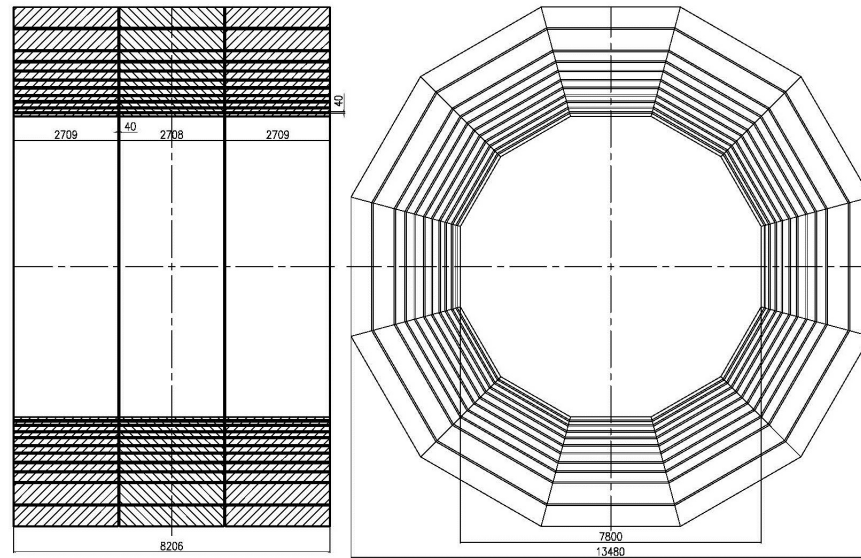

Figure 6.3: The barrel yoke design

The end-cap yokes are designed to dodecagonal structure with the out diameter of 13,300 mm. Each end-cap yoke will consist of 11 layers and one pole tip (Fig. 6.4). Each end-cap yoke is composed of 12 segments. The thickness of pole tip is 600 mm, and from the inner to the outer, the layer thicknesses are 80 mm, 80 mm, 120 mm, 120 mm, 160 mm, 160 mm, 200 mm, 200 mm, 240 mm, 540 mm, 540 mm, respectively.

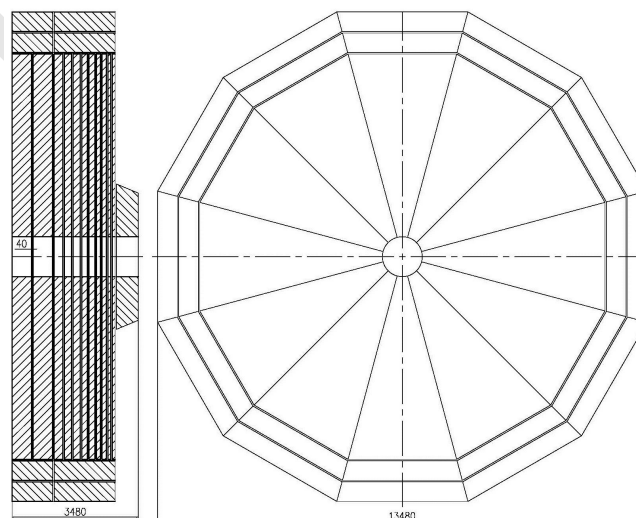

Figure 6.4: The end-cap yokes design

6.5 R&D

6.5.1 HTS solenoid concept for IDEA detector

A large HTS solenoid concept is proposed for the IDEA detector, which requires a thin solenoid with a magnetic field of 2 Tesla and a room temperature bore of 2.1 m diameter [chapter 3.2.2][3, 4]. The HTS solenoid is supposed to use YBCO stacked-tape cable as the conductor. The radiation length of single YBCO tape coated with 150 μm copper is about 0.014 X0. 35 YBCO tapes stacked together allows 25 kA and 0.49 X0. If the operation temperature of the cold mass is raised to 20 K, the heat conductivity parameters of all components are improved. In addition, the electricity consumption of cooling station will be much lower than that at 4.2 K. Therefore, the YBCO stacked-tape cable and the cryogenics are brought into R&D.

6.5.2 Dual Solenoid Design

The dual solenoid design is presented for a conceptual option for CEPC detector magnet, which contains two series connected superconducting solenoids carrying the opposite direction current, based on FCC twin solenoid [5]. The main solenoid provides central field within the room temperature bore. The outer solenoid provides the stray field shielding and a magnetic field between the two solenoids to facilitate muon tracking. The main advantage of this dual solenoid is that the system becomes comparatively light-weight and cost saving without iron yoke. The sketch is shown in Figure 6.5.

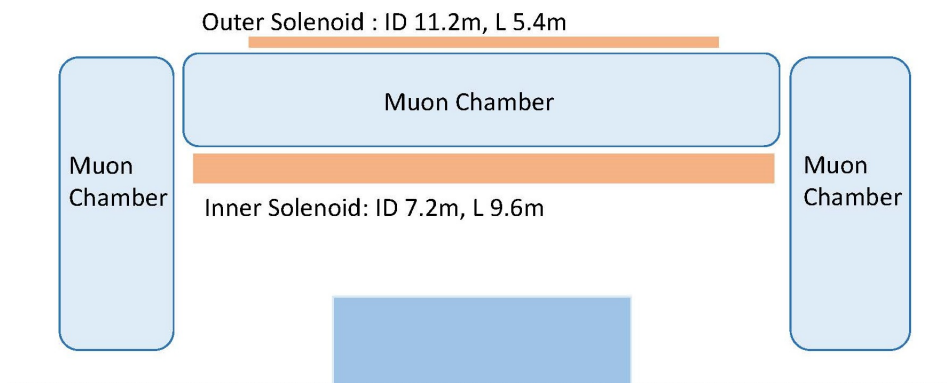

Figure 6.5: The sketch of dual solenoid design

6.5.3 Superconducting Conductor

The coil is simulated with an elasto-plastic 2D FE model. Mechanical analysis requires the experimental material properties of all conductor components. We have developed a 10 m long NbTi Rutherford cable embedded inside stabilizer from a manufacturer which provides I_c 5 kA at 4 T background magnetic field. Meanwhile we measured the material properties and the tensile stress of 10 m cable. Longer conductor with higher I_c 15 kA at 4 T background is ongoing.

6.5.4 Thermosyphon Circuit

Thermosyphon principle is used to cool CEPC detector superconducting magnet by the U-shaped circuit configuration carrying LHe on the outer surfaces of the coil supporting cylinders. The thermosyphon circuit consists of helium phase separator located in an elevated position and the cooling tubes. In order to study the phase transition process of helium in the circuit, the changes of the temperature distribution and the density distribution over the time, a 1:10 scale thermosyphon circuit will be established for simulation and experiment.

CHAPTER 7

MUON SYSTEM

The muon system for a CEPC detector is designed to identify and measure muons, and will be located within the solenoid flux return yoke of the whole spectrometer. Two detector concepts are envisaged for the CEPC collider and they will likely employ different muon systems. A common requirement for the muon detectors will be to identify muons with very high efficiency ($\geq 95\%$) and high purity, over the largest possible solid angle and down to low p_T values (≥ 3 GeV/c). A standalone muon momentum resolution from the muon detector could be required, translating in a good position resolution along the muon track which would add robustness and redundancy to the whole detector design. In particular the muon system will significantly help in identifying muon produced within jets, for example from b decays.

The muon system plays an important role in measuring physics processes involving muon final states, e.g. $e^+e^- \rightarrow ZH$ with $Z \rightarrow e^+e^-$ or $\mu^+\mu^-$ and also for studying long-lived particles that would decay far from the primary vertex but still within the detector. In addition, the muon system compensates for leaking energetic showers and late showering pions from the calorimeters, which could help to improve the relative jet energy resolution[1].

In this chapter the baseline muon system design is described and then two possible technologies for realising the muon detector are presented, specifically the Resistive Plate Chamber (RPC) and an innovative type of Micro Pattern Gas detector (MPGD), the μ -RWELL detector. The main difference between the two technologies lies in the position resolution and the cost. More layers of RPC detectors are needed to achieve a good momentum resolution on the muon tracks with respect to the μ -RWELL case, where 3-4 layers would be sufficient. In terms of rate capability both technologies are more than adequate for the CEPC environment. If the requirement of a standalone muon momentum

resolution from the muon detector is relaxed, the number of layers of the RPC solution could be greatly reduced. Other gas detectors are also being considered as possible options, such as Gas Electron Multiplier (GEM), MicroMegas and Monitored Drift Tubes (MDT), although they are not described here.

7.1 Baseline Design

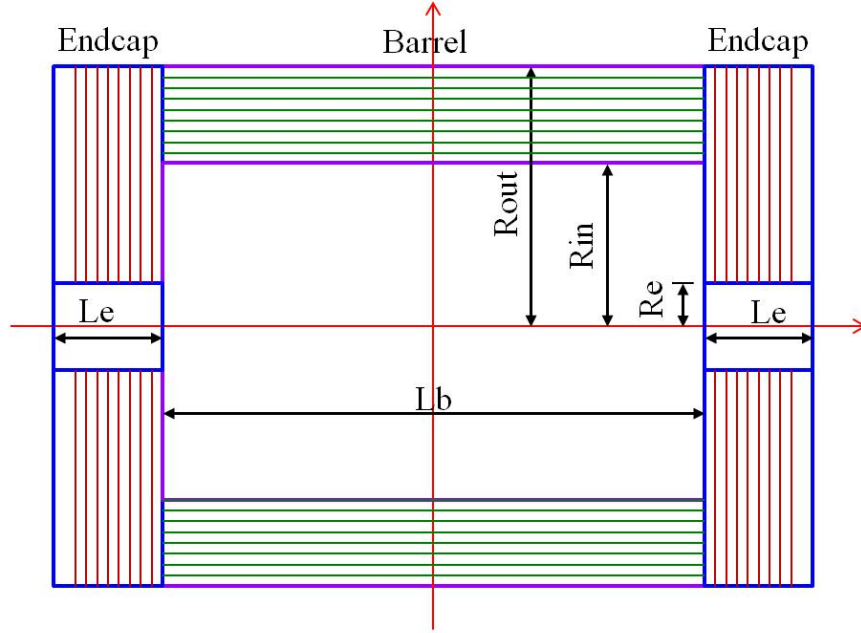

Figure 5.1: The basic layout of the muon system.

The CEPC muon system is the outermost component of the whole detector. It is divided into barrel and end-caps, as shown in Fig. 5.1. Both the barrel and end-caps consist of segmented modules. The segmentation is constrained by the maximum sizes of the module and sensitive unit (more segments are required for a larger detector), dodecagon segmentation is selected for the baseline design of the CEPC muon system. All baseline design parameters are summarised in Table 7.1. These parameters will be further optimised together with the inner detectors, in particular the ECAL and the HCAL.

The number of sensitive layers and the thickness of iron (or tungsten) in the absorbers are two critical parameters. For the baseline design, the total thickness of iron absorber is chosen to be 8λ (the nuclear interaction length of iron) distributed in 8 layers, which should be sufficient for effective muon tracking together in combination with the calorimeters. Gaps of 4 cm between neighbouring iron layers give adequate space for installing sensitive detectors.

The solid angle coverage of the CEPC muon system should be up to $0.98 \times 4\pi$ in accordance with the tracking system. Minimum position resolutions of $\sigma_{r\phi} = 2.0$ cm and $\sigma_z = 1.5$ cm are required. Since the particle flow algorithm calorimetry provides very good particle identification capabilities, the detection efficiency of 95% ($E_\mu > 5$ GeV) of the CEPC muon system should provide enough redundancy and complement in muon detection for most physics processes related to muons. The muon system should provide

Table 7.1: The baseline design parameters of the CEPC muon system

Parameter	Possible range	Baseline
Lb/2 [m]	3.6 – 5.6	4.0
Rin [m]	3.5 – 5.0	4.4
Rout [m]	5.5 – 7.2	7.0
Le [m]	2.0 – 3.0	2.6
Re [m]	0.6 – 1.0	0.8
Segmentation	8/10/12	12
Number of layers	3 – 10	8
Total thickness of iron	6 – 10 λ ($\lambda = 16.77$ cm)	8 λ (136 cm) (8/8/12/12/16/16/20/20/24) cm
Solid angle coverage	(0.94 – 0.98) $\times 4\pi$	0.98
Position resolution [cm]	$\sigma_{r\phi}$: 1.5 – 2.5	2
	σ_z : 1 – 2	1.5
Time resolution [ns]	< 10	1 – 2
Detection efficiency ($E_\mu > 5$ GeV)	92% – 99%	95%
Fake($\pi \rightarrow \mu$)@30GeV	0.5% – 3%	< 1%
Rate capability [Hz/cm ²]	50 – 100	~60
Technology	RPC	RPC (super module, 1 layer readout, 2 layers of RPC)
	μ RWell	
Total area [m ²]	Barrel	~4450
	Endcap	~4150
	Total	~8600

several hits each with a spatial resolution of a few cm, a time resolution of a few ns and a rate capability of 50 – 100 Hz/cm². Based on the dimensions and segmentation of the baseline design, the total sensitive area of the muon system amounts to 8600 m².

7.2 The Resistive Plate Chamber technology

Resistive Plate Chamber (RPC) is suitable for building large area detectors with centimeter spatial resolution. It has been applied in muon systems for experiments including BaBar [2], Belle [3], CMS [4], ATLAS [5], BESIII [6], and Daya Bay [7]. It provides a common solution with the following advantages: low cost, robustness, easy construction of large areas, large signal, simple front-end electronics, good time and spatial resolution. It is chosen as the baseline design of the CEPC muon system.

RPCs can be built with glass or Bakelite, and run in avalanche or streamer mode. Bakelite RPCs of about 1200 m² and 3200 m² were produced for the BESIII and Daya Bay muon systems, respectively. Compared with glass RPC, Bakelite RPC has the advantages of easier construction, lower density, larger cell size and lower cost, especially if the event rate is below 100 Hz/cm² as required by the CEPC muon system. The characteristics of Bakelite and glass RPCs are compared in Table 7.2. Further improvements are required for Bakelite RPCs, however, in terms of long-term stability, detection efficiency, readout technologies, lower resistivity ($< 10^{10}$) and higher rate capability.

Table 7.2: Comparison of Bakelite and glass RPC.

Parameters		Bakelite	Glass
Bulk resistivity [$\Omega \cdot \text{cm}$]	Normal	$10^{10} \sim 10^{12}$	$> 10^{12}$
	Developing	$10^8 \sim 10^9$	
Max unit size (2 mm thick) [m]		1.2×2.4	1.0×1.2
Surface flatness [nm]		< 500	< 100
Density [g/cm ³]		1.36	2.4~2.8
Min board thickness [mm]		1.0	0.2
Mechanical performance		Tough	Fragile
Rate capability [Hz/cm ²]	Streamer	100@92%	
	Avalanche	10K	100@95%
Noise rate [Hz/cm ²]	Streamer	< 0.8	0.05

7.3 The μ -RWELL technology

The μ -RWELL is a compact, spark-protected and single amplification stage Micro-Pattern Gas Detector (MPGD). A μ -RWELL detector [8] is composed of two PCBs: a standard GEM Drift PCB acting as the cathode and a μ -RWELL PCB that couples in a unique structure the electron amplification (a WELL patterned matrix) and the readout stages 7.2a). A standard GEM 50 μm polyimide foil is copper clad on one side and Diamond Like Carbon (DLC) sputtered on the opposite side. The thickness of the DLC layer is adjusted

according to the desired surface resistivity value ($50\text{-}200\text{ M}\Omega/\square$) and represents the bottom of the WELL matrix providing discharge suppression as well as current evacuation. The foil is then coupled to a readout board 7.2b). A chemical etching process is then performed on the top surface of the overall structure in order to create the WELL pattern (conical channels $70\text{ }\mu\text{m}$ ($50\text{ }\mu\text{m}$) top (bottom) in diameter and $140\text{ }\mu\text{m}$ pitch) that constitutes the amplification stage 7.3. The high voltage applied between the copper and the resistive DLC layers produces the required electric field within the WELLS that is necessary to develop charge amplification. The signal is capacitively collected at the readout strips/pads. Two main schemes for the resistive layer can be envisaged: a *low-rate* scheme (for particles fluxes lower than $100\text{ kHz}/\text{cm}^2$) based on a simple resistive layer of suitable resistivity; and an *high-rate* scheme (for a particle flux up to $1\text{ MHz}/\text{cm}^2$) based on two resistive layers intra-connected by vias and connected to ground through the readout electrodes. Finally, a drift thickness of 3-4 mm allows for reaching a full efficiency while maintaining a versatile detector compactness.

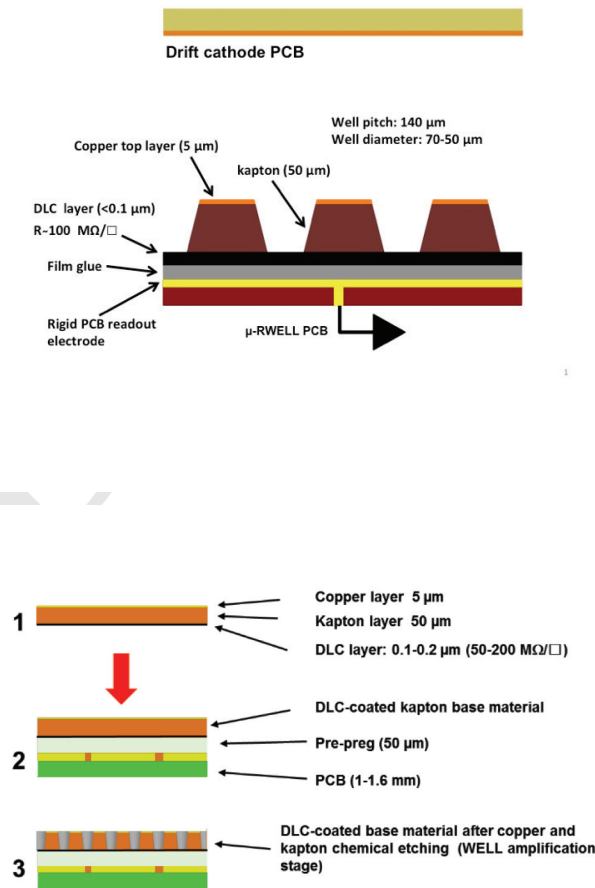

Figure 7.2: a) Layout of a μ -RWELL detector module; b) Coupling steps of the μ -RWELL PCB c) Amplification stage directly coupled with the readout.

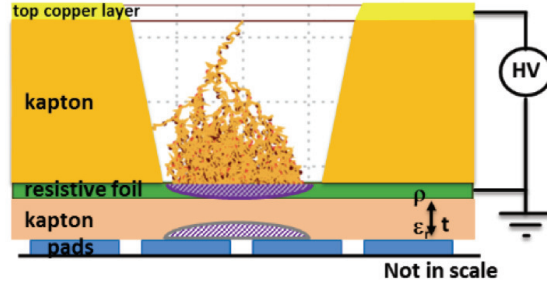

Figure 7.3: Amplification stage directly coupled with the readout.

A distinctive advantage of the proposed μ -RWELL technology is that the detector does not require complex and time-consuming assembly procedures (neither stretching nor gluing), and is definitely much simpler than many other existing MPGDs, such as GEMs or MicroMegs. Being composed of only two main components, the cathode and anode PCBs, is extremely simple to be assembled. This makes the cost of a μ -RWELL detector typically less than half the cost of a triple-GEM detector of the same size and the same strip pitch.

The μ -RWELL technology, especially in its *low-rate* version, is a mature solution, with whom single detectors of a 0.5 m^2 have been realised and successfully operated in the laboratory as well as in test beams. They can withstand particle rates up to a few tens of kHz/cm^2 , providing a position resolution as good as $\sim 60 \text{ }\mu\text{m}$ with a time resolution of 5-6 ns. The detailed results are presented in the Appendix. The requirements of a muon detector for CEPC are not as stringent and therefore can be easily and cost-effectively achieved with the μ -RWELL technology. Moreover the μ -RWELL technology is a robust solution, intrinsically safer against sparks than, for example, the widely used GEM detectors. The muon system could be realised by using tiles of μ -RWELL detectors of a size $50 \times 50 \text{ cm}^2$. This would make the whole muon detector very modular with components bought directly from industry. A CEPC muon detector made of μ -RWELL tiles could consist of three or four detector layers stations, each equipped with a couple of layers of μ -RWELL detectors in order to provide a very precise, of the order of $200\text{-}300 \mu\text{m}$, position resolution on the coordinates of a muon track.

7.4 Future R&D

The baseline conceptual design and most promising technologies for the CEPC muon system have been discussed. Future R&D requires detailed studies of different technologies and further optimization of baseline design parameters. Several critical R&D items have been identified, including:

- **Long-lived particles optimization:** Explore new physics scenario of long-lived particles and exotic decays. Optimize detector parameters and technologies.
- **Layout and geometry optimization:** Detailed studies on the structure of the segments and modules need to be carried out to minimise the dead area and to optimise the interface for routing, support and assembly. The geometry and dimensions need to be optimized together with the inner detectors, in particular the ECAL and the HCAL.
- **Detector optimization:** Study aging effects, improve long-term reliability and stability, readout technologies.
- **Detector industrialization:** Improve massive and large area production procedures for all technologies. One example is the engineering and the following industrialization of the μ -RWELL technology. The engineering of the detector essentially coincides with the technological transfer of the manufacturing process of the anode PCB and the etching of the kapton foil to suitable industrial partners.

CHAPTER 8

READOUT ELECTRONICS AND DATA ACQUISITION

8.1 Readout electronics

This [1] is an example with plots, please edit ...

8.2 Data Acquisition System

The DAQ system for CEPC has to fulfill the needs of a high luminosity and large scale experiment without compromising on rare or yet unknown physics processes. The main task of the DAQ system is to readout data from the frontend electronics with the level-1 trigger decision given by trigger system, then build into a full event with data fragment from different detector area and do data process, such as data compress and data quality monitoring. Finally data is sent to the permanent storage.

8.2.1 System Requirements

8.2.1.1 Readout Data Rate Estimation

The proposed CEPC detector is similar with ILC detector. There are four sub-detectors in current conceptual design: VTX, TPC, ECAL and HCAL.

The table ?? shows the estimated data rate of sub-detectors of CEPC. Event rate reaches to $\sim 32\text{ k Hz}$ with hadron and Bhabha events with the 2 Tesla solenoid option ($L=3.2 \times 10^{35} \text{ cm}^2/\text{s}$). So we assume a maximum event rate of 100 kHz. But the readout time of VTX and silicon tracker is about $20 \mu\text{s}$, so the maximum read out rate is 50 kHz. With level-1 trigger, the total raw data rate is 2-4 TBytes/s.

8.2.1.2 Data Process Requirements

The purpose of the online event processing will mainly be event classification, data quality monitoring and online filter to reduce background events. Event building will be performed on the online farm connected to front-end electronics via the commercial network switch. An event filter will also run on online farm. Each node of the online farm will process the data of one complete event at a time.

8.2.2 Conceptual Design Schema

The LHC experiments have up to 10^8 front-end readout channels and a maximum event building rate of 100 kHz, moving data with up to 300 GB/s (with an average throughput of < 200 GB/s required). The proposed CEPC DAQ system has the similar requirement in terms of data throughput. But the computing requirements for event processing at the CEPC, in terms of storage and CPU, are depend on the algorithm. Another reason to hard to give the final design is the rapid developing of computing and network market.

The figure 8.1 shows the conceptual software architecture design of CEPC DAQ based on the experience gained from BESIII and DayaBay experiments. The DAQ system is connected with frontend electronics through network switch with TCP/IP protocol. The network switches connected to frontend electronics are located near detectors and electronics. All other DAQ switches and computers are deployed at computer room. The backend computer farm is connected with front switches through multiple fibers. The DAQ system will provide other common functions like run control, run monitoring, information sharing, distributed process manager, software configure, bookkeeping, Elog, data quality monitoring, remote monitoring and so on.

	Channels or cells	Occupancy %	Hits	Nbit/hit	Volume MBytes/evt	Readout rate kHz

Table 8.1: CEPC DAQ Data Rate Estimation.

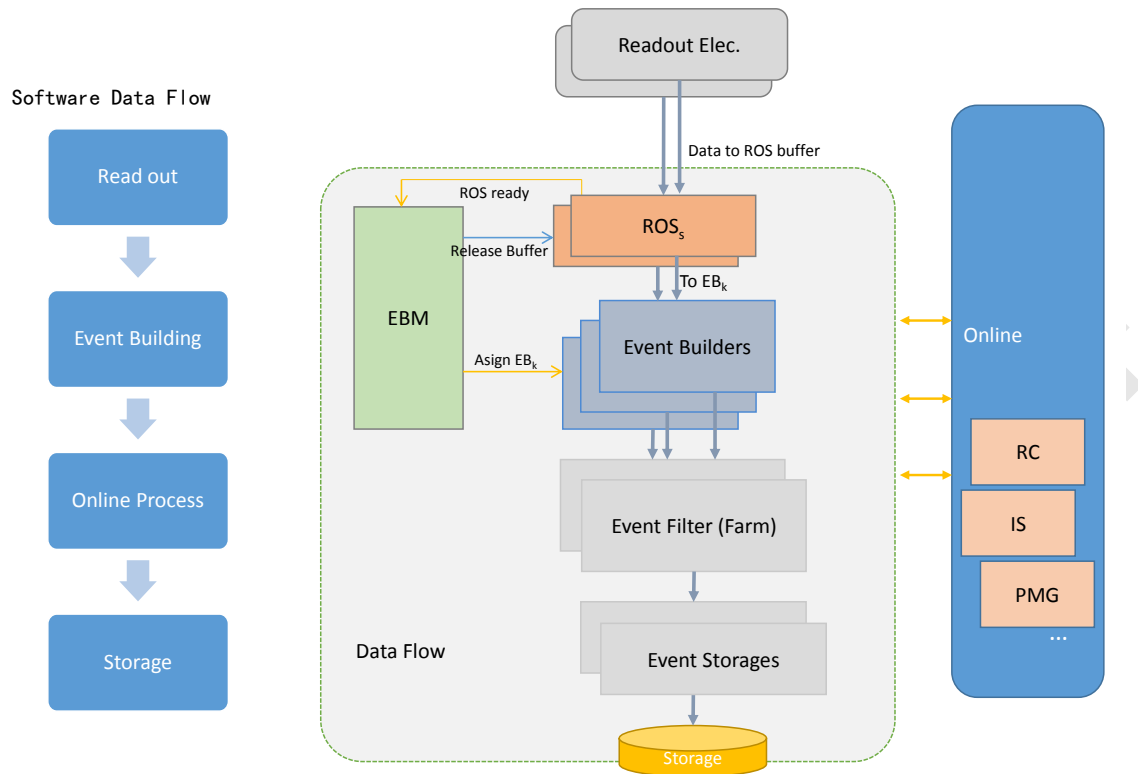

Figure 8.1: DAQ Conceptual Software Architecture Design Diagram

There are two levels of event building in CEPC DAQ data flow system. The first level is implemented in readout farm which reads out the data from frontend electronics and builds into a data fragment. The second level implemented in online farm which reads out the data from readout farms and builds into a full event. The two levels of event building could refer to BESIII event building as followed:

1. electronics boards send data to ROS(read out system) through network.
2. ROS receive all data slice of one event and send event id to EBM(event building manager).
3. EBM assign event id to a free EB(event builder) node when EBM get all same event id from all ROSs.
4. EB send data request to each ROSs.
5. ROSs send requested data to EB.
6. EB receive all ROSs data fragments of one event and finish full event building, then send event id back to EBM.
7. EBM send event id to ROSs to clear data buffer.

The software trigger can be deployed at event filter farm. Each event filter node requests a full event from EBs, then sends the event data to process tasks to analyze for

Draft: Wednesday 1st August, 2018-03:54

software trigger and data quality monitoring, at last sends triggered event to event storage nodes.

CHAPTER 9

MACHINE DETECTOR INTERFACE

Machine-Detector Interface (MDI) represents one of the most challenging topics for the CEPC projects. In general, it will have to cover all common issues relevant to both the machine and detector. Topics summarized in this chapter include the interaction region, the final focusing magnets, the detector radiation backgrounds and the luminosity instrumentation. Integration of all the machine and detector components in the interaction region is also briefly discussed. It is critical to achieve comprehensive understanding of MDI issues and assure the optimal performance of the machine and detector.

9.1 Interaction region

The interaction region (IR) has to focus both electron and positron beams to small spot sizes at the interaction point (IP) to maximize the machine luminosity, and merge but subsequently separate the two beams which travel in two separate storage rings. The IR layout, as illustrated in Fig. 9.1, has received several necessary updates with respect to the published preliminary CDR [1], to cope with the latest double-ring design and a beam-crossing angle of 33 mrad. The two final focusing magnets, QD0 and QF1, sits inside the detector. The focal length (L^*), defined as the distance from the final focusing magnet (*i.e.* QD0) to the IP, has increased from 1.5 m to 2.2 m. This allows enlarged separation between the two single apertures of the QD0. Compensating magnets are positioned in front of the QD0 and surrounding both the QD0 and QF1 magnets. They are introduced to cancel out the detector solenoid field and minimize the disturbance on the focusing beams. Furthermore, the outer radius of the compensating magnets defines the detector acceptance to be $|\cos \theta| \leq 0.993$. The luminosity calorimeter (so called “LumiCal”), located right in front of the compensating magnets, is designed to measure the integrated

luminosity to a precision of 10^{-3} or even higher. Tracking disks, labeled as FTD, are designed to measure charged particle trajectories in the forward region.

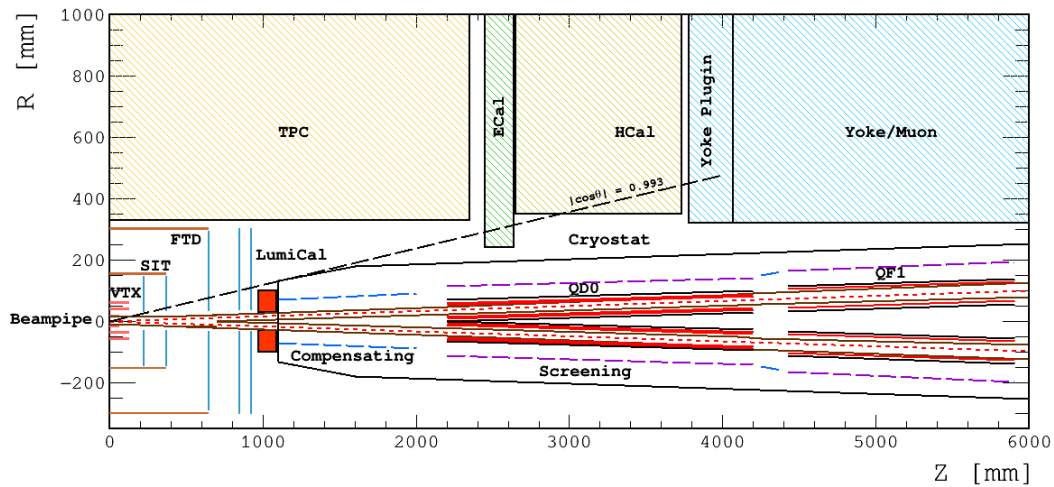

Figure 9.1: Layout of the CEPC interaction region.

9.2 Final focusing magnets

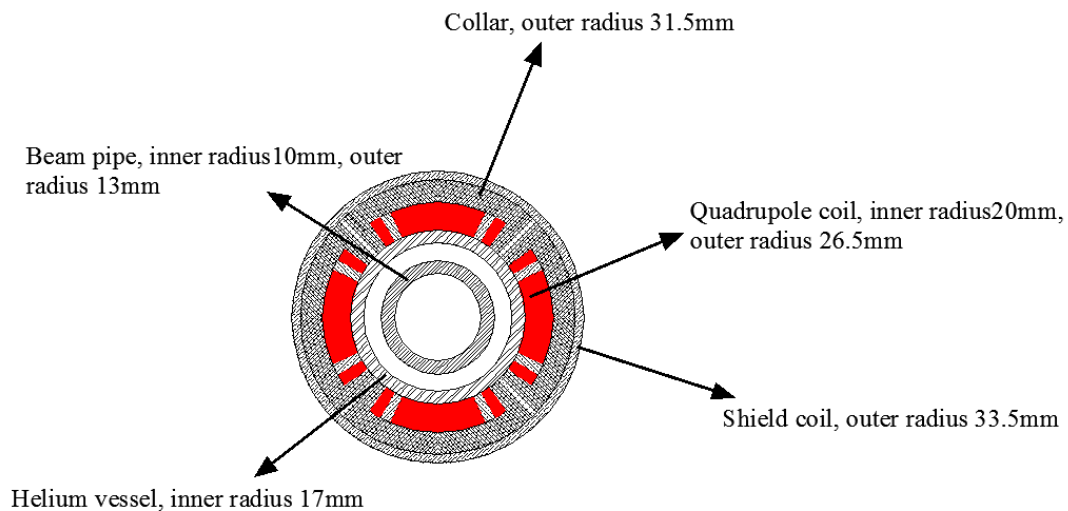

Figure 9.2: Schematic view of the single aperture of the QD0 superconducting magnet.

In the interaction region, compact high gradient quadrupole magnets are designed to focus the electron and positron beams. The two final focusing quadrupoles (QD0 and QF1), are placed inside the CEPC detector and must operate in the background field of the detector solenoid. QD0 is the quadrupole magnet close to the interaction point, with a distance of 2.2 m to the IP. It is designed as a double aperture superconducting magnet and can be realized with two layers of Cos-Theta quadrupole coil using NbTi Rutherford cables without iron yoke. The cross-sectional view of the single aperture of the QD0 is shown in Fig. 9.2. It is designed to deliver a gradient field of 136 T/m and control the filed

harmonics in the sensitive area to be below 3×10^{-4} . Design parameters are summarized in Table 9.1. The QF1 magnet is similar to the QD0, except that there is an iron yoke around the quadrupole coil for the QF1.

Table 9.1: Main design parameters of QD0 and QF1.

Magnet	QD0	QF1
Field gradient [T/m]	136	110
Magnetic length [m]	2.0	1.48
Coil turns per pole	23	29
Excitation current [A]	2510	2250
Coil layers	2	2
Stored energy [kJ]	25.0	30.5
Inductance [H]	0.008	0.012
Peak field in coil [T]	3.3	3.8
Coil inner diameter [mm]	40	56
Coil outer diameter [mm]	53	69
X direction Lorentz force/octant [kN]	68	110
Y direction Lorentz force/octant [kN]	-140	-120

Additional compensating magnets are introduced to minimize the disturbance from the detector solenoid on the incoming and outgoing beams. The compensating magnets in front of the QD0 is designed to achieve an almost zero integral longitudinal field before entering the QD0. And the compensating magnet right outside the QD0 and QF1 is necessary to screen the detector field. The magnets are based on wound of rectangular NbTi-Cu conductors. To minimize the magnet size, the compensating magnets are segmented into 22 sections with different inner coil diameters. Inside the first section, the central field reaches the peak value of 7.2 Tesla. More detailed design of the final focusing magnets and the compensating magnets can be found in [2].

9.3 Detector backgrounds

Beam and machine induced radiation backgrounds can be the primary concern for the detector design [3–6]. They can cause various radiation damages to the detectors and electronic components, and degrade the detection performance or even kill the detector completely in the extreme case. During data-taking, high rate radiation backgrounds may significantly increase the detector occupancy and exaggerate the data-taking capability of the impaired detector. Therefore it is always desirable to characterize the potential backgrounds at the machine and detector design stage and mitigate their impacts with effective measures. Detailed Monte Carlo simulation, along with lessons and experience learned from other experiments, can serve as the basis for such studies.

The deleterious effects of the radiation backgrounds can be represented with hit density, total ionizing dose (TID), and non-ionizing energy loss (NIEL). The expected hit

density can be used to evaluate the detector occupancy. TID is an important quantity for understanding surface damage effects in electronics. NIEL, represented in the 1 MeV neutron equivalent fluence, is important for understanding the bulk damage to silicon devices. The background simulation starts with either generating background particles directly in the IR (e.g. pair production) or propagating them to the region close enough to the IR (e.g. SR photons and off-energy beam particles). Particle interactions with detector components are simulated with Geant4 [7–9]. The characterization methodology for the ATLAS detector background estimation [10] has been adopted. In the following, main radiation backgrounds originating from synchrotron radiation, beam-beam interactions, and off-energy beam particles, are discussed and their contributions are carefully evaluated.

9.3.1 Synchrotron radiation

Synchrotron radiation (SR) photons are vital at circular machines. At the CEPC, they are mostly produced in the last bending dipole magnets and in the focusing quadrupoles inside the interaction region. The innermost tracking detectors can be sensitive to photons above 10 keV and vulnerable to high levels of soft photon radiation¹. In order to reduce the energy and flux of SR photons that enter the straight sections, the field strength of the last bending dipole magnet has been reduced and becomes much weaker than the normal arc dipole fields. This controls the critical energy of SR photons to be below 100 keV and makes the collimation design less difficult.

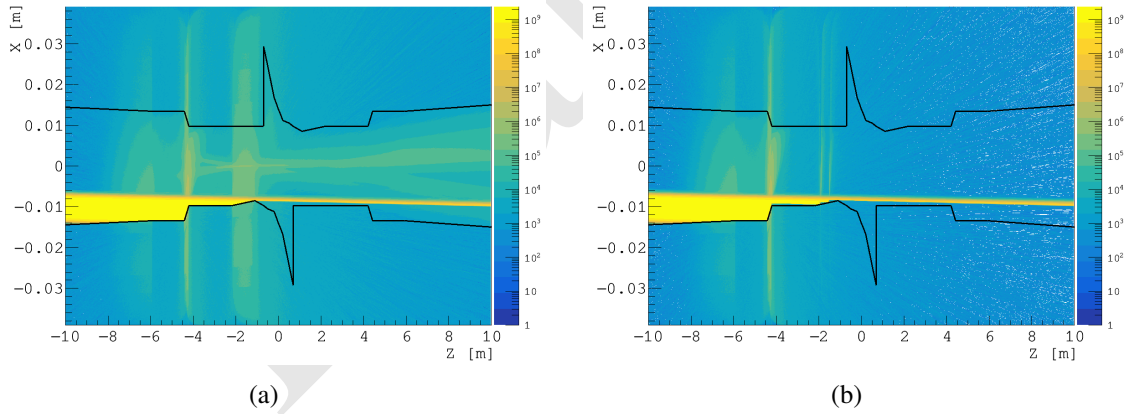

Figure 9.3: Distribution of the synchrotron photon flux formed by the upstream bending magnet on the left side before (a) and after (b) introducing collimators.

The BDSim [11] software based on GEANT4 has been deployed for the detailed studies. It allows generating SR photons from the relevant magnetic elements and transports them to the region of the experimental detectors. Particular care has been taken for a realistic simulation in the tails of the beam density distributions (up to $10 \sigma_{x/y}$) and for both beam core and halo, as particles from the tails are most effective in producing background particles. SR photons from the last dipole magnet form the light yellow band in Fig. 9.3 and can hit the beam pipe in the interaction region. A considerable amount of

¹It should be noted that the SR photon energy increases rapidly with the beam energy and additional measures might have to be introduced to allow detector operation at higher operation energies.

them are scattered and can hit the central Beryllium beam pipe ($z = \pm 7$ cm) as shown in Fig. 9.3(a). Collimators made with high- Z materials (e.g. tungsten) and particular shapes are designed to block those scattering photons. Three sets of mask tips, located at $|z| = 1.51, 1.93$ and 4.2 m along the beam pipe to the interaction point, are introduced to suppress such SR photons. They can effectively reduce the number of SR photons hitting the central beam pipe from nearly 40, 000 to below 80. This reduction leads to much lower power deposition in the beam pipe and allows a simplified cooling design for the beam pipe. The resulting photon flux distribution after collimation is shown in Fig. 9.3(b). SR photons generated in the final focusing magnets are also carefully evaluated. They are highly forward and do not strike directly the central beam pipe unless the particles are $40 \sigma_x$ off the central orbit.

Table 9.2: The input machine parameters to the GUINEA-PIG simulation.

Machine Parameters	H (240 GeV)	W (160 GeV)	Z (91 GeV)
Beam energy [GeV]	120	80	45.5
Particles per bunch [10^{10}]	15	12	8
Transverse size σ_x/σ_y [μm]	20.9/0.068	13.9/0.049	6.0/0.078
Bunch length σ_z [μm]	3260	5900	8500
Emittance $\varepsilon_x/\varepsilon_y$ [nm]	12.1/0.0031	0.54/0.0016	0.18/0.004

9.3.2 Beam-beam interactions

Beamstrahlung and its subsequent process of pair production are important background at the CEPC. Due to the pinch effect in the beam-beam interaction, the trajectories of beam particles in the bunches are bent, which causes the emission of beamstrahlung photons. This process has been studied with the Monte Carlo simulation program GUINEA-PIG [12], which takes into account dynamically changing bunch effects, reduced particle energies and their impacts on the electric and magnetic fields. In addition, the simulation program has been customized to implement the external detector field for the charged particle tracking. This allows improved determination of the positions and momenta of the out-going charged particles before interfacing to the GEANT4 detector simulation. Machine parameters for operation at different energies are listed in Table 9.2, and serve as the input to the GUINEA-PIG simulation. It should be noted that compared to other consequent processes, electron-positron pair production generates most significant detector backgrounds. The processes can be categorized as:

- *Coherent Production:* e^+e^- pairs are produced via the interaction of virtual or real photons (e.g. beamstrahlung photons) with the coherent field of the oncoming bunch. Particles can be highly energetic but are dominantly produced with small angle and confined in the beam pipe.
- *Incoherent Production:* e^+e^- pairs are produced through interactions involving two real and/or virtual photons. Most of the particles are confined in the beam pipe by the strong detector solenoid field. However, a small fraction of them are produced with high transverse momentum and large polar angle.

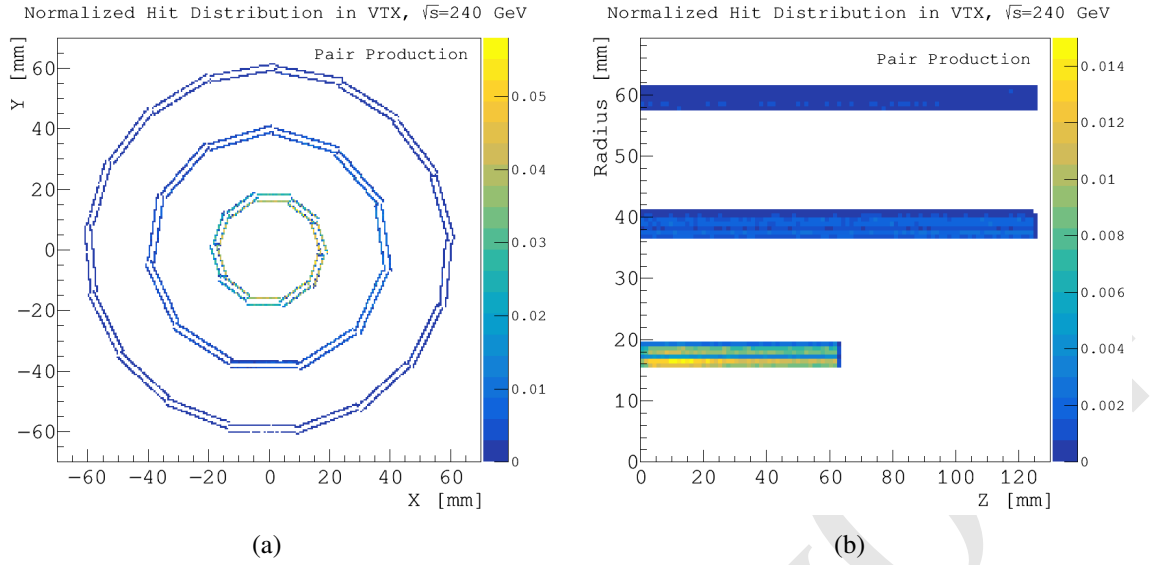

Figure 9.4: Hit distributions due to the pair production in the $x-y$ and $r-z$ planes of the vertex detector.

As shown in Fig. 9.4(a), the resulting hit distribution is nearly uniform in the ϕ -direction, even though the beam squeezing is different in the x and y directions. On the other hand, the hit distribution is more dense in the central region as shown in Fig. 9.4(b), but decreases rapidly with the increased radius.

Table 9.3: Maximum radiation backgrounds originating from the pair production at each vertex detector layer.

	Hit Density [hits/BX]	TID [kRad/year]	NIEL [1 MeV n_{eq} /cm ² ·year]
Layer 1 ($r = 1.6$ cm)	2.2	620	1.2×10^{12}
Layer 2 ($r = 1.8$ cm)	1.5	480	9.1×10^{11}
Layer 3 ($r = 3.7$ cm)	0.18	60	1.2×10^{11}
Layer 4 ($r = 3.9$ cm)	0.15	45	1.0×10^{11}
Layer 5 ($r = 5.8$ cm)	0.03	9.7	3.3×10^{10}
Layer 6 ($r = 6.0$ cm)	0.02	6.8	3.0×10^{10}

9.3.3 Off-energy beam particles

Circulating beam particles can lose significant amounts of energy in scattering processes. If exceeding 1.5% of the nominal energy (defined as the machine energy acceptance), scattered particles can be kicked off their orbit. A fraction them will get lost close to or in the interaction region. They can interact with machine and/or detector components and contribute to the radiation backgrounds. There are three main scattering processes that

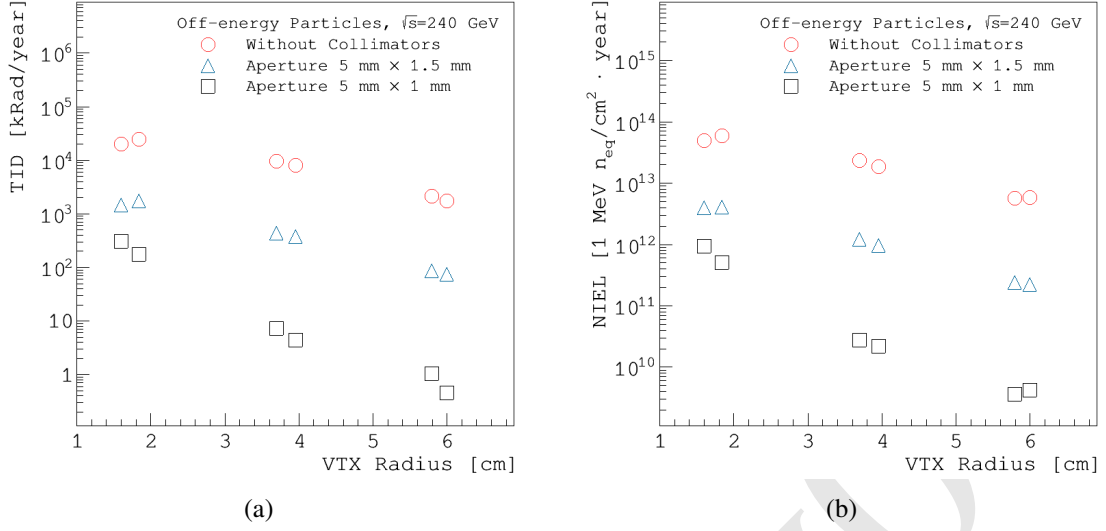

Figure 9.5: Contributions to TID and NIEL from off-energy beam particles are effectively reduced after introducing the two sets of collimators.

are almost entirely responsible for the losses of beam particles, including beamstrahlung, radiative Bhabha scattering and beam-gas interaction.

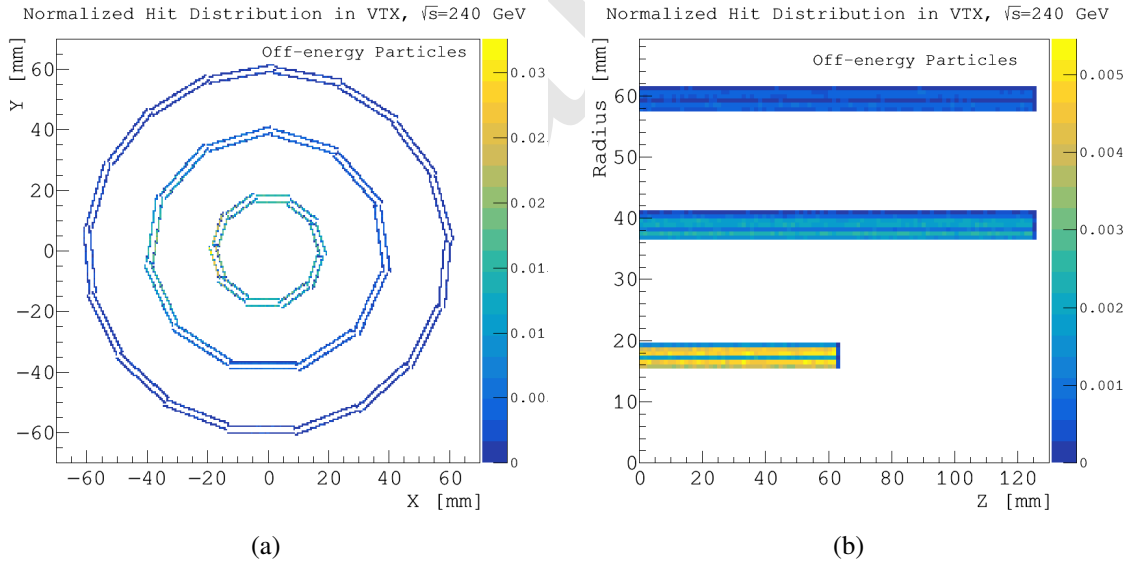

Figure 9.6: Hit distributions due to the radiative Bhabha scattering process in the $x - y$ and $r - z$ planes of the vertex detector.

While beamstrahlung events out of beam-beam interactions are generated with GUINEA-PIG, radiative Bhabha events with small angles are generated with the BBBREM program [13]. Interactions between the beam particles and the residual gas in the beam pipe are simulated with custom code, assuming the gas pressure to be 10^{-7} mbar. The backgrounds originating from the beam-gas interaction is much smaller compared to that from the Radiative Bhabha scattering. Beam particles after interactions are tracked with

SAD [14] and transported to the interaction region. Particles lost close to the interaction region, either right after the bunch crossing or after traveling multiple turns, are interfaced to detector simulation.

Backgrounds introduced by off-energy beam particles can be effectively suppressed with proper collimation. The designed collimator aperture has to be small enough to stop as much as possible the off-energy beam particles, but must be sufficiently large without disturbing the beam. Two sets of collimator pairs, APTX1/Y1 and APTX2/Y2 are placed in the arch region, with aperture size of 5 mm and 1 mm, in the horizontal and vertical planes, respectively. They are equivalently $14 \sigma_x$ and $39 \sigma_y$, which are sufficiently away from the beam clearance region. Fig. 9.5 shows off-energy beam particles entering the IR are reduced significantly after introducing the collimation system. As shown in Fig. 9.6(a), the resulting hit distribution maximizes towards the $-x$ direction due to the nature of the off-energy beam particles that are swept away by the magnets. But along the z direction, the hit distribution is more or less uniform with the additional contribution of the back-scattered particles by the LumiCal in the downstream. For the background estimation, the maximum values in the $-x$ direction are taken. At the first vertex detector layer ($r = 1.6$ cm), the hit density is about 0.22 hits/cm² per bunch crossing from the radiative Bhabha scattering. The TID and NIEL are 310 kRad per year and 9.3×10^{11} 1 MeV n_{eq} /cm² per year, respectively.

9.3.4 Summary of radiation backgrounds

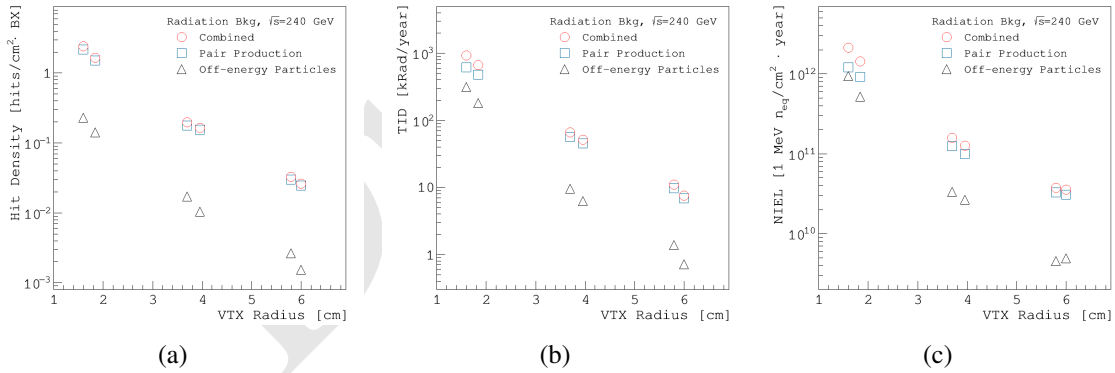

Figure 9.7: Hit density, TID and NIEL at different vertex detector layers due to the pair production, off-energy beam particles and the two combined.

When operating the machine at the center-of-mass energy of $\sqrt{s} = 240$ GeV, the main detector backgrounds come from the pair-production. The contribution from the off-energy particles is nearly an order of magnitude lower. Fig. 9.7 shows the hit density, TID and NIEL at different vertex detector layers, originating from the pair production, off-energy beam particles and the two combined. In addition, TID and NIEL distributions covering the silicon detectors in $r - z$ are shown in Fig. 9.7.

At lower operation energies, *i.e.* $\sqrt{s} = 160$ GeV for W and $\sqrt{s} = 91$ GeV for Z , the background particles are usually produced with lower energies but with higher rates given the higher machine luminosities. In addition, the pair-production dominates the radiation backgrounds and contributions from other sources become negligible. The

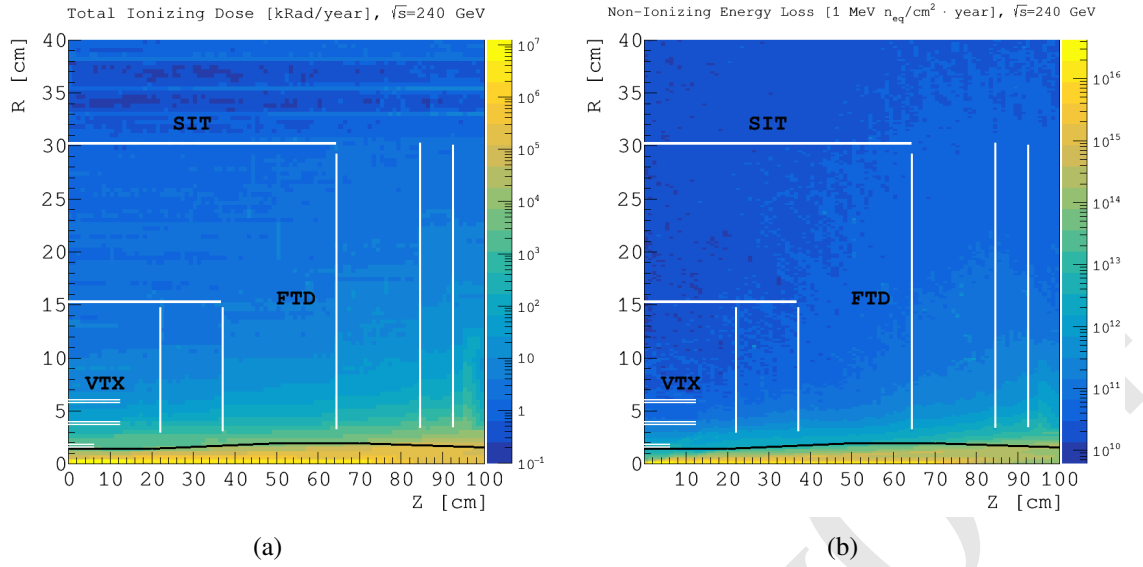

Figure 9.8: TID and NIEL distribution in $r - z$ for the machine operation at $\sqrt{s} = 240$ GeV.

resulting radiation backgrounds at the first vertex detector layer at different operation energies are summarized in Table 9.4.

Table 9.4: Summary of radiation background levels at the first vertex detector layer ($r = 1.6$ cm) at different machine operation energies.

	H (240)	W (160)	Z (91)
Hit Density [hits/BX]	2.4	2.3	0.25
TID [MRad/year]	0.93	2.9	3.4
NIEL [10^{12} 1 MeV $n_{eq}/\text{cm}^2 \cdot \text{year}$]	2.1	5.5	6.2

9.4 Luminosity instrumentation

Very forward region at CEPC will be instrumented with a luminometer (LumiCal), aiming to measure integral luminosity with a precision of 10^{-3} and 10^{-4} in e^+e^- collisions at the center-of-mass energy of 240 GeV and at the Z pole, respectively. The precision requirements on the integral luminosity measurement are motivated by the CEPC physics program, intended to test the validity scale of the Standard Model through precision measurements in the Higgs and the electroweak sectors with 10^6 Higgs and 10^{10} Z bosons. Many sensitive observables for such measurements critically depend on the uncertainty of the integral luminosity.

Luminosity at an e^+e^- collider is best measured by counting the Bhabha events of elastic e^+e^- scattering. Its theoretical interpretation is better than 0.05% at the Z pole [15]. The scattered electrons are distributed in the forward direction with a $1/\theta^3$ dependence. The cross section of the BHLUMI [16] simulation is illustrated in Fig. 9.9(a).

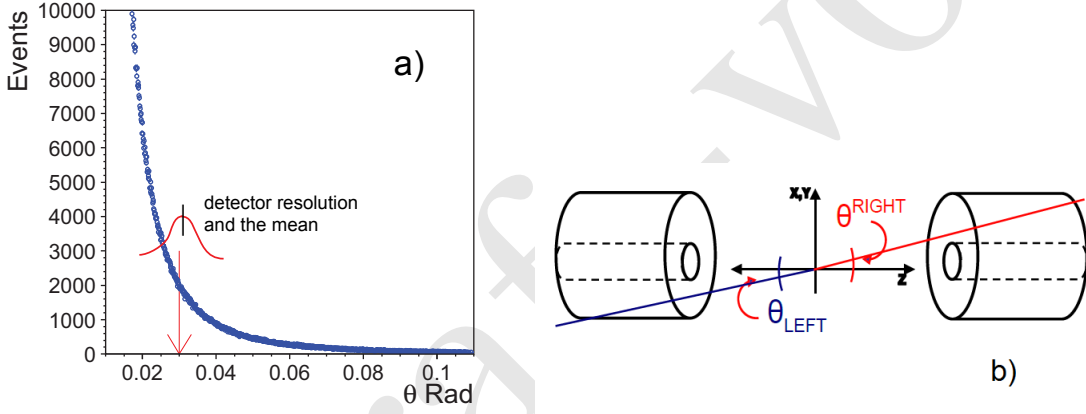

Figure 9.9: a) Distribution of scattered electrons in azimuthal angle of the BHLUMI simulation. The Gaussian curve illustrates the detector resolution to θ measured at a given fiducial edge. The offset of the mean in measurement contributes to the systematic errors. b) Bhabha events are measured preferably in the forward direction of the e^+e^- collision characterized by the back-to-back of elastic scattering and the electromagnetic shower of the electrons.

A Bhabha event is detected with a pair of scattered electrons back-to-back in direction, and the momenta of beam energy. Therefore the luminosity detector consists of a pair of forward calorimeters with high precision on detecting electron impact positions. The configuration is sketched in Fig. 9.9(b). Bhabha events are detected in the angular coverage ($\theta_{min} < \theta < \theta_{max}$) of the forward calorimeters. The integrated luminosity (L) of the leading order calculation is

$$\sigma^{vis} = \frac{16\pi\alpha^2}{s} \left(\frac{1}{\theta_{min}^2} - \frac{1}{\theta_{max}^2} \right), \quad \mathcal{L} = \frac{1}{\epsilon} \frac{N_{acc}}{\sigma^{vis}}, \quad \frac{\Delta\mathcal{L}}{\mathcal{L}} \sim \frac{2\Delta\theta}{\theta_{min}}, \quad (9.1)$$

where ϵ is the detection efficiency to be evaluated. The systematic uncertainties are contributed mostly by the error on θ_{min} , mainly due to mechanical alignment and the detector resolution. The error propagates to the luminosity is about twice on magnitude.

The dimension of the detector is favorable to have the θ_{min} as low as possible to optimize coverage of the Bhabha cross section. The position of the luminosity detector is planned to be mounted in front of the quadrupole magnets at $z = \pm 100$ cm. With the

θ_{min} of ~ 30 mrad, corresponding to a radius of 30 mm to the beam pipe at $z = 100$ cm, the cross-section, σ^{vis} , after event selection will reach ~ 50 nb. A large detector coverage of σ^{vis} is necessary for statistics required for the Z line-shape study, where the $Z \rightarrow qq$ cross section is 41 nb. The precision required for 10^{-4} makes a strong demand on the detector resolution. At $\theta = 30$ mrad, it corresponds to an offset of $\Delta\theta \sim 1.5 \mu\text{rad}$, which is equivalent to $1.5 \mu\text{m}$ in radius at $z = 100$ cm.

Several technological options for LumiCal design are under study, as described in Sec. 9.4.1, with emphases on the precision of polar angle and energy reconstruction of Bhabha particles scattered in the t -channel $V(V = \gamma, Z)$ exchange. The dual beam-pipe configuration with the beam-crossing at 33 mrad results to a boost to particles of e^+e^- collisions. The back-to-back characteristics of Bhabha electrons is shifted by approximately a horizontal offset of 33 mm. The impact to LumiCal design is discussed. The LumiCal together with the quadrupole magnet are inserted into the tracking volume that extended to $z = \pm 200$ cm. Shower leakage of electrons off the LumiCal to central tracker is studied by simulation, which is also discussed.

Luminometer at CEPC is a precision device with challenging requirements on the mechanics and position control. Precision requirements on integral luminosity measurement set the precision of the opening aperture and positioning control of the LumiCal. Various sources of luminosity uncertainty in this respect are reviewed in Sec. 9.4.2. Encouraging estimations on feasibility of the luminosity precision goals are presented. Detailed studies are ongoing, to include the full simulation of physics and machine induced processes and of the detector itself, for various luminometer positioning and technology choices.

9.4.1 Technological and design options

In the current design of the very forward region at CEPC, luminometer is foreseen to cover the polar angle region between 26 mrad and 105 mrad what translates into the detector aperture of 25 mm for the inner radius and 100 mm for the outer, at $z = \pm 100$ cm of the LumiCal front plane from the IP. The detector options shall be considered for

1. precision of the electron impact position to $r \sim 10 \mu\text{m}$ ($1 \mu\text{m}$) for the errors on luminosity, corresponding to the systematic errors on luminosity of $\Delta L \sim 10^{-3}$ (10^{-4}) in the Higgs (Z -pole) operations;
2. monitoring of the detector alignment and calibration of detector position by tracking of Bhabha electrons with upstream detectors;
3. energy resolution and separation of e/γ for measurements of single photons and radiative Bhabha events;
4. maximum coverage and segmentation of the LumiCal to accommodate the dual beam-pipe and the beam crossing of 33 mrad;
5. minimizing shower leakage into the central tracking volume.

The detector option for the $1 \mu\text{m}$ precision on electron impact position is very much limited silicon detectors segmented in strips or pixels. Silicon strip detectors of $50 \mu\text{m}$ readout pitch is commonly reaching a resolution of $\sigma \sim 5 \mu\text{m}$. The mean on error

($\bar{\sigma} = \sigma/\sqrt{n}$) would be much smaller. The selection of Bhabha events is set on a fiducial edge of θ_{min} , for example, center in the gap between two silicon strips. The systematic error is therefore the number of events being selected with an error of $\bar{\sigma}$ despite the detector resolution, and would be relatively small, which is indicated by the Gaussian curve in Fig. 9.9(a). The alignment of the detector position would be the major systematic requirement for an absolute precision of $1 \mu\text{m}$.

A conceptional Luminosity detector is illustrated in Fig. 9.10 for the combination of a silicon detector and a calorimeter around the beam pipe for measurement of the electron impact position energy. The segmentation of the calorimeter is considered for the back-to-back resolution detecting a pair of Bhabha electrons, and for separation of e/γ in case of radiative photon accompanied with the electron or from beam background. The thickness is determined for the energy resolution favorable of $> 20X_0$ for shower containment of a 50 GeV electron. The option on the calorimeter is limited by the space affordable. The traditional crystal or scintillator-based calorimeter will require more than 20 cm in length for $> 20X_0$. The most compact design would be a sandwiched stack of Silicon samplers with Tungsten in $1X_0$ (3.5 mm thick), to a total of about 10 cm that weights about 400 kg.

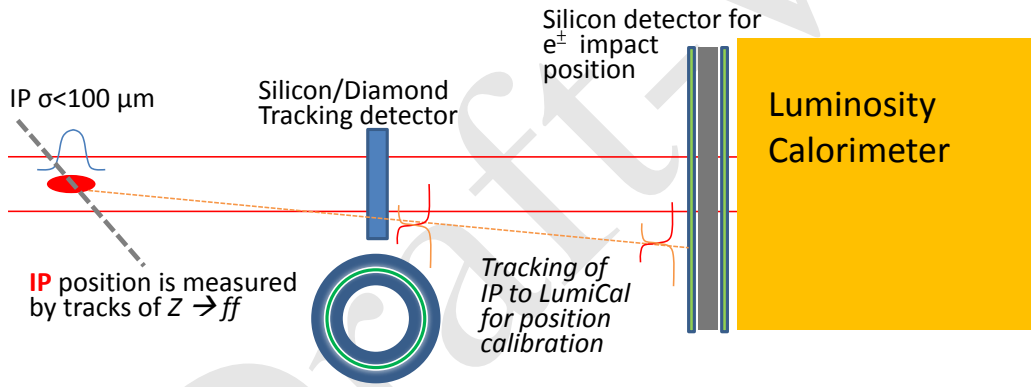

Figure 9.10: A conceptional luminosity detector combination with a upstream silicon/diamond detector for tracking Bhabha electrons to calibrate position of the luminosity detector.

The alignment precision of the front-layer Silicon detector is the most critical issue to reach $1 \mu\text{m}$ in radius for the luminosity measurement of 10^{-4} . For the precision at the $1 \mu\text{m}$ level, a monitoring system with laser alignment is required to calibrate the detector position. The θ angle of a detected electron is calculated assuming an IP position measured by the beam steering and the central tracking system. The IP position relative to the luminosity detector could be limited to survey relative to central tracking devices or beam pipe. If feasible, a tracking system on the Bhabha electrons will improve very the measurement precision of the electron theta angle. This is illustrated in Fig. 9.10 for the option that a ring of silicon or diamond detector is mounted in front of the Luminosity detector. Such that a electron track is measure from the IP, the ring detector, and the LumiCal impact position. The ring detector offers a second survey, and by extrapolation, to calibrate the LumiCal silicon strip positions.

The front silicon layer of the luminosity detector will measure electron impact positions to a few micron. If this will be a fine-pitch strip detector, the position is measured by strips collecting the ionization charges generated by a traversing electron. In Fig. 9.11,

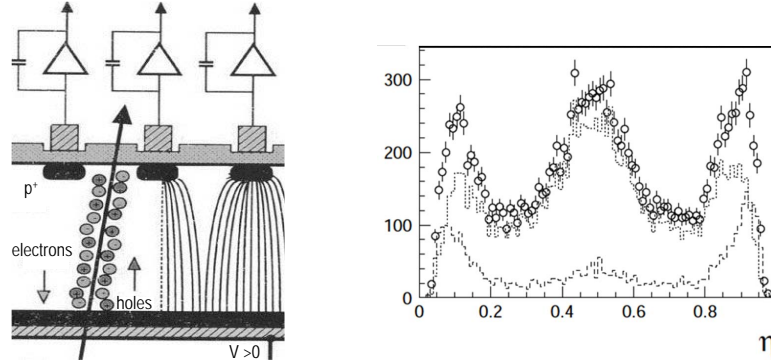

Figure 9.11: Charge collection by silicon strips is illustrated for ionization charges generated by a traversing particle. The $\eta = Q_r / (Q_r + Q_l)$ distributions are made for charge sharing to left and right strips to the impact position, for a test devices with strips implementation in $25 \mu\text{m}$ pitch and the readout of every other strips in $50 \mu\text{m}$ pitch. The η distributions are also plotted for contents with charges collected by two-strip (dotted) and three-strip (dashed) cases. The middle bump corresponds to the position of the floating strip between two readout strips.

the charge sharing is illustrated for $\eta = Q_r / (Q_r + Q_l)$ with the ionization charges collected by the strips on the right (left) of the impact position. The distribution is collected for a test device having the strips implanted in $25 \mu\text{m}$ pitch, and the readout in $50 \mu\text{m}$ pitch by wire bonding to every other strips. The floating strip between two readout strips attracts charges drifting towards it and results to the bump at $\eta \sim 0.5$, in particular for a wide cluster of charges collected by three strips (dotted line). The impact position of a particle is approximated by center-of-gravity weighted on the charges between two strips. With the η distribution, the non-linear distribution can be corrected to achieve a position resolution of better than $\sim 5 \mu\text{m}$ for the readout pitch of $50 \mu\text{m}$. With the strip detectors placed in a magnetic field, the ionization charge in the silicon wafer is drifted toward one side, and therefore the η distribution is tilted un-evenly. Without a proper correction for the η , the true impact position the off-set can be as large as half the readout pitch.

If the luminosity detector will be assembled in a sandwiched silicon-tungsten calorimeter with the type of silicon wafer for the front layer. Wide silicon strips may be chosen in a case like the OPAL LumiCal [17], applying 2.5 mm wide strips in circular span of 11.25° . The resolution on detection of an electron, as well as for e/γ separation is at the 1 mm level. Assuming that the event counting of Bhabha electrons has the fiducial edge, θ_{min} , chosen at the middle between two strips, and the events are evenly divided to left and right strips without charge sharing. The systematic error to luminosity measurement is by the alignment error of the strip position of a few microns, and is not by the resolution.

Charge sharing between the gap of two-strips have been studied with prototype wafers[18] shown in Fig. 9.12. The wafer dimension is $65 \times 65 \text{ mm}^2$ implemented with 2 mm wide strips and the gaps from $50 \mu\text{m}$ to $160 \mu\text{m}$. The beam test was conducted with a set of fine-pitch strip detectors as a telescope to provide reference positions of incident electrons scattered across strips and gaps. The charge sharing for electrons in the gaps are compared for η distributions in Fig. 9.12, which are found compatible for the different gap widths. Charge collection shows no loss, and are drifted toward the near strips with the η peaking at the edges. The dispelling charges in the middle of a gap is difficult for deriving

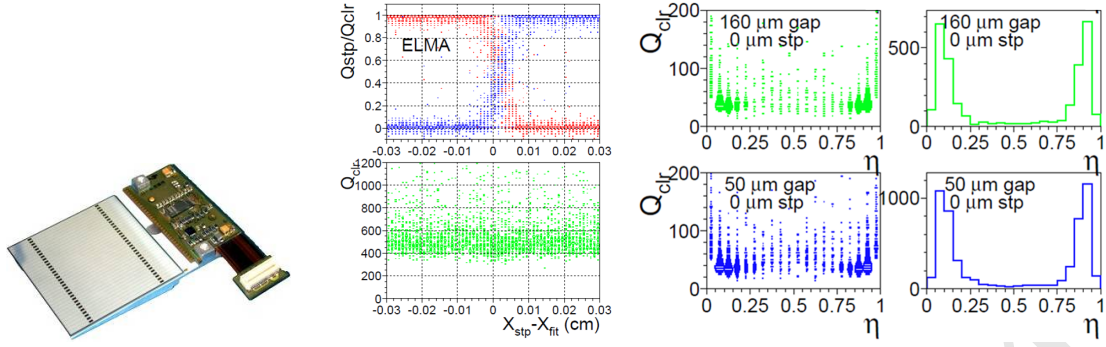

Figure 9.12: Beam tests using prototype silicon wafer of the CMS pre-shower detector (right) were conducted for collection of ionization charges generated by traversing particles across the gap between strips. The charge sharing by adjacent strips are plotted (middle) to the reference impact position (extrapolation of a upstream telescope). The sum strip charges (middle plots) is compatible to the hits on a strip. The charge sharing in $\eta Q_r/(Q_r + Q_l)$ peaks near 0 and 1, indicating non-linear response to the randomly distributed beam particles across the gap.

the position of an incident electron in the gap. But, it does divide the event fraction cleanly to the near side of the strips.

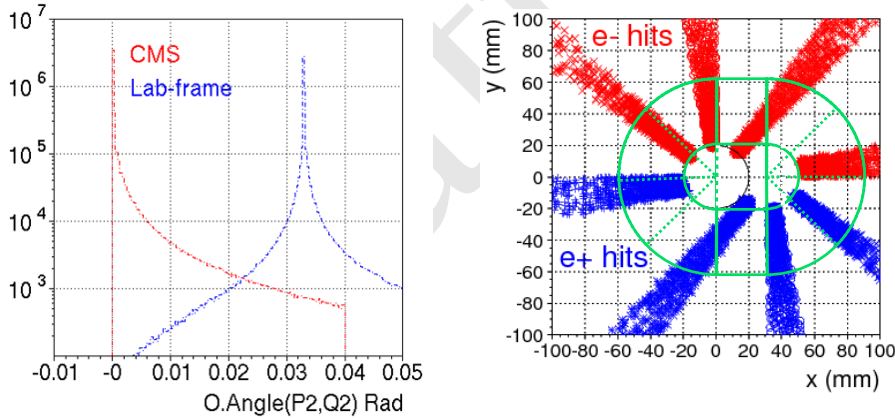

Figure 9.13: Bhabha events of BHLUMI simulation at the Z-pole are plotted for the back-to-back opening angle of scattered electron-position pairs in Center-of-Mass and the laboratory frames (left). The impact positions on the LumiCal front face are plotted in slides of ϕ angles every 45 degrees (right). The detector coverage is illustrated in green lines indicating a beam-pipe of 20 mm, extended from beam center at $x = \pm 16.5$ mm.

The double ring configuration of the CEPC machine design at the interaction point has a beam crossing angle of 33 mrad. The effect to the electrons of Bhabha interaction is a boost off the accelerator ring center, by maximum 16.5 mrad in horizontal direction. The distribution is simulated with the BHLUMI program. The shift on back-to-back angle is plotted in Fig. 9.13. The boost is toward $+x$ direction of the laboratory frame. The electron impact positions on the LumiCal front-layer at $z = 100$ cm are also plotted in Fig. 9.13, in slices of every 45 degrees to indicate the dependence on p_T direction. The beam-pipe centers are at $x = \pm 16.5$ mm. The green lines indicate the beam-pipe area of 20 mm in radius extending horizontally, and the coverage of the LumiCal in segmentation

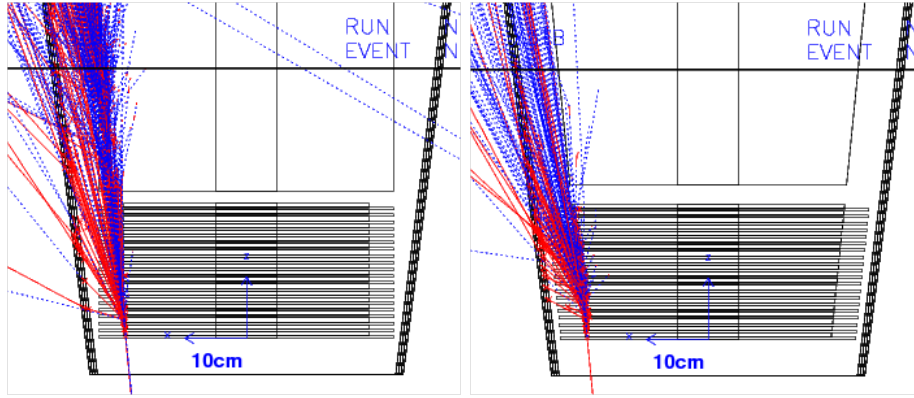

Figure 9.14: Event display of a GEANT simulation for electron shower on the LumiCal configuration stacked with 20 decks of silicon and Tungsten layers in TUBE and CONE shapes.

of circular and rectangular silicon wafers. The electron impact positions are illustrated for >20 mrad to the laboratory frame. Electrons of low scattering angles, in particular for those in $-x$ direction, are lost into beam-pipe. To have both scattered electrons and positrons detected, the corresponding θ_{min} on the horizontal axis is the beam-pipe acceptance plus 16.5 mrad. The loss of events on vertical direction is much less. With a beam pipe as indicated with $\pm y$ dimension equals radius, the horizontal boost is not losing electrons with a larger y -position. A large detector coverage for Bhabha events is most favorable. The large opening of beam-pipe position is inevitable. We shall pursue the vertical dimension to be low as possible for a total integrated Bhabha cross section of larger than 50 nb.

The LumiCal mounted in front of the quadrupole magnet at $z = \pm 100$ cm is half way in the tracking volume of $z = \pm 200$ cm. Shower leakage of electrons at the edge of LumiCal is investigated with a GEANT simulation with parameters cross-checked with a lateral shower study [19]. The LumiCal is configured assuming a sandwiched Silicon-Tungsten calorimeter stacked in twenty decks of 2 mm air-gap and $1X_0$ tungsten (3.5 mm thick). The air-gap has a layer of silicon wafer of 0.3 mm thick. The front layer of the LumiCal is positioned at $z = 100$ cm. The geometry of the LumiCal is tested in two configurations: a TUBE with uniform inner and outer radii of 25 and 100 mm, respectively; and a CONE shape with the outer edge at a constant angle of $\arctan 0.1$ to the interaction point. The CONE shape is intended for well separated absorption of electron shower in a theta threshold. Illustrated in Fig. 9.14 are the event display of the simulations. Out of the LumiCal, a 5 mm iron cone at $|\cos \theta| = 0.992$ is implemented for absorption of low energy shower secondaries massing into the center tracking volume.

The TUBE configuration leaves a corner of about 5 mrad on the outer edge, where the shower leakage of an incident electron is with energetic shower secondaries. The CONE shape allows the shower fully developed once the electron enters the calorimeter coverage. The shower leakage reaching the Fe-cone is recorded for the particle energies arriving and penetrating through, which are listed in Table 9.5 for 50 GeV and 125 GeV electrons. When the shower is well contained, the leakage is just a few dozens of less than 30 MeV particles. A shower on the edge creates up to 3k secondaries into the tracking

volume mostly of less than 100 MeV. The 5 mm iron layer can filter a large fraction of them, to less than 1k particles traversing through.

9.4.2 Systematic effects

The main measure of luminosity at CEPC is the count of Bhabha events N_{Bh} detected in coincidence in the two halves of the luminosity calorimeter LumiCal. The luminosity figure is then obtained from the equation of $\mathcal{L} = N_{\text{acc}}/\sigma^{\text{vis}}$. The cross section for the Bhabha process, σ_{vis} , should be integrated over the same phase space as used for the counting of Bhabha events. The limited precision with which the experimental acceptance region is defined gives rise to a number of systematic effects. Further, other processes misidentified as Bhabha and the limited accuracy of the theoretical calculation of σ_{vis} contribute to the overall systematic uncertainty.

A generator-level study was performed to assess the effects related to the precision of the Bhabha acceptance region on Bhabha counting. An underlying assumption of the study is that the LumiCal is centered on the outgoing beam axis. This assumption is essential for data-driven control of the radial offset of Lumical with respect to the IP, as well as for Bhabha event counting based on the mirrored asymmetric polar-angle acceptance regions on the left and right side of the detector [17] (in further text, *OPAL-style selection*). OPAL-style counting cancels out biases due to left-right asymmetries of the experimental angular acceptance. It is further assumed that for the final state particles hitting the radial region between 50 mm and 75 mm, corresponding to the detector fiducial volume (FV), shower leakage has a negligible effect on the reconstruction of the polar angle and the energy.

Bhabha event samples are generated using the BHLUMI generator [16]. Center-of-mass (CM) energy of 240 GeV is assumed, roughly corresponding to the peak of the Higgs production cross section. The particles are generated in the range of polar angles including a ~ 7 mrad margin outside the FV to allow non-collinear final state radiation (FSR) to contribute to the events. After event generation, smearing is applied to the final particle vertices and momenta according to the nominal CEPC parameters. Additional smearing or bias is then applied according to one systematic effect at a time. Four mo-

Table 9.5: Number of particles leaking out of the LumiCal outer radius (N_{enter}) and number of particles passing through the Fe-cone (N_{pass}). Two different detector designs (TUBE and CONE) and two shower energies (50 GeV and 125 GeV) are simulated.

	50 GeV electrons		125 GeV electrons	
	TUBE	CONE	TUBE	CONE
θ (mrad)	$N_{\text{enter}}/N_{\text{pass}}$	$N_{\text{enter}}/N_{\text{pass}}$	$N_{\text{enter}}/N_{\text{pass}}$	$N_{\text{enter}}/N_{\text{pass}}$
40	15.4/5.6	13.6/5.8	38.0/16.0	35.8/14.7
90	392/155	173/76	1028/399	434/19.7
95	501/290	367/152	2389/720	937/382
98	762/216	860/284	1718/473	2176/725
99	553/140	1331/367	1102/273	3306/915

menta of close-by particles are summed up to account for cluster merging in LumiCal. The selection criteria to count an event consist of the OPAL-style angular selection and the requirement that the energy of both detected showers is above 50% of the nominal beam energy. The relative acceptance bias is determined as the relative difference between the Bhabha count $N_{\text{Bh},i}$ obtained with the inclusion of the considered effect i and N_{Bh} obtained with the nominal set of parameters.

Table 9.6 lists the requirements on beam delivery, MDI and LumiCal installation, needed to limit individual systematic effects in the luminosity measurement to 1×10^{-3} , such as required for the Higgs program at CEPC. Parameters influencing the integral luminosity precision are given as follows:

- ΔE_{CM} , uncertainty of the available CM energy affecting the Bhabha cross-section,
- $E_{e^+} - E_{e^-}$, asymmetry of the incident beam energies resulting in a net longitudinal boost of the event,
- $\frac{\delta \sigma_{E_{\text{beam}}}}{\sigma_{E_{\text{beam}}}}$, uncertainty of the beam energy spread,
- Δx_{IP} and Δz_{IP} , radial and axial offsets of the IP w.r.t. the LumiCal,
- Beam synchronization, resulting in axial offset of the IP w.r.t. the LumiCal,
- $\sigma_{x_{\text{IP}}}$ and $\sigma_{z_{\text{IP}}}$, radial and axial fluctuations of the scattering position,
- r_{in} , inner radius of the LumiCal acceptance region,
- $\sigma_{r_{\text{shower}}}$, reconstruction precision of the radial shower coordinate,
- Δd_{IP} , uncertainty of the distance between the luminometer halves.

Most requirements are technically feasible with the present state of the art of accelerator and detector technology. The most important challenge identified is the precision of the inner acceptance radius r_{in} of LumiCal. In order to keep the luminosity precision of 1 permille, r_{in} must be known to within $10 \mu\text{m}$. The precision requirement of r_{in} scales linearly with the required luminosity precision, implying a correspondingly stricter requirement for the Z -pole run.

9.4.3 Summary on LumiCal

Instrumentation of the very forward region is very important for the realization of the CEPC physics program. Several technology options are under consideration. Some of them have been successfully applied at LEP or are under study at other future projects. We argue that a tracker placed in front of the luminometer can improve polar angle measurement accuracy, facilitate LumiCal alignment and enable electron-photon separation. Luminometer must be centered on the outgoing beam axis to allow control of the systematic effects at the required level. Precision requirements on beam delivery, MDI and LumiCal installation have been addressed by simulation, and proven to be feasible with the present state-of-the-art of accelerator and detector technology.

Table 9.6: Requirements on beam delivery, MDI and LumiCal installation, needed to limit individual systematic effects to 1×10^{-3} .

Parameter	Unit	Limit
ΔE_{CM}	MeV	120
$E_{e^+} - E_{e^-}$	MeV	240
$\delta\sigma_{E_{\text{beam}}}$		effect canceled
$\sigma_{E_{\text{beam}}}$		
Δx_{IP}	mm	>1
Δz_{IP}	mm	10
Beam synchronization	ps	7
$\sigma_{x_{\text{IP}}}$	mm	1
$\sigma_{z_{\text{IP}}}$	mm	10
r_{in}	mm	10
$\sigma_{r_{\text{shower}}}$	mm	1
Δd_{IP}	μm	500

9.5 Detector integration

Both QD0 and QF1 are located inside the detector, which drastically complicates the support and alignment of the detector and machine components in the interaction region. The two final focus magnets and the LumiCal will possibly be mounted on a dedicated support structure, extended from a pillar outside the detector and suspended from the solenoid cryostat. They might have to be integrated together before being pushed into the interaction region. The amount of material in front of the LumiCal must be minimized so that the high precision of the LumiCal can be maintained. This shall inventively introduce more difficulties to the detector integration. Furthermore, the shaped beam pipe and surrounded silicon detectors will possibly be supported from a structure of carbon fiber reinforced plastic, which can hang at the flanges of the field cage of the Time Projection Chamber (TPC). Significant effort is required to realize a solid mechanical design and to define a reasonable procedure for the detector and machine installation scheme.

CHAPTER 10

PHYSICS OBJECTS PERFORMANCE

10.1 Introduction

This chapter reports the baseline detector performance of the physics object reconstruction at the full simulation level. The physics performance is also determined by the reconstruction algorithms, which including the tracking, the particle flow, and the high-level reconstruction algorithms.

All the samples used in this chapter are the generated with the official CEPC software and simulated with the baseline detector geometry, except for the photon reconstruction a simplified geometry is also used to quantify the impact of geometry defects.

Starting with a brief introduction of the official CEPC software and reconstruction algorithms in section 10.2, this chapter reports the performance on each individual physics objects, and demonstrated with the corresponding Higgs signal distributions.

10.2 The CEPC software

The reconstruction is vital for the high energy physics experiment. Comparing to the conventional reconstruction at the collider experiments, the Particle Flow reconstruction interprets the information from every subsystem coherently and is much complicated. A Particle Flow algorithm, Arbor [?] [?], has been developed, and an entire simulation-reconstruction software chain has been established accordingly, as shown in Fig 10.1.

10.2.1 The generator, the simulation, and the digitization modules

The CEPC software uses the Whizard [?] as its major generator. The Whizard is a widely used generator for the linear collider studies. In cooperating with the whizard

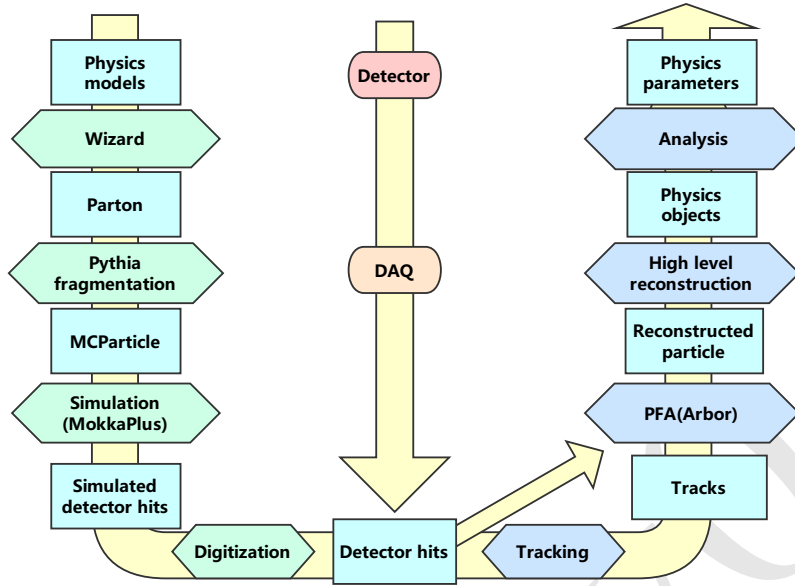

Figure 10.1: Information flow at the CEPC simulation studies

team, dedicated CEPC beam parametrization has been established in its official release. The Whizard generator is used for the SM processes, including both Higgs signal and all the SM backgrounds. Meanwhile, Madgraph [?] and Pythia [?] are used to generate New Physics samples.

The MokkaPlus is the official Geant4 Simulation software for the CEPC. MokkaPlus is a virtual geometry constructor that compiled with the Geant4 libraries [?] and mysql database [?]. The MokkaPlus is developed from the Mokka [?], the obsoleted simulation framework used in linear collider studies. Many new functions have been added to the MokkaPlus and all the CEPC detector models are implemented into MokkaPlus.

The digitization algorithm should properly model the amplification procedure and the time-dependent patterns of the sub-detector. These dedicated models need to be established and tuned according to experimental data. The digitization algorithm is sub-detector dependent and technology dependent. We developed a general calorimeter digitization algorithm for both APODIS ECAL and HCAL, which could precisely reproduce the test beam results [?]. The tracker digitization modules are inherited from the ilcsoft, whose parameters are adjusted for the optimization studies to the sub-detectors.

10.2.2 The reconstruction modules

The reconstruction chain includes the tracking, the Particle Flow, and the high level reconstruction algorithms. The tracker hits are reconstructed into tracks via the tracking modules. The particle flow algorithm reads the reconstructed tracks and the calorimeter hits, and builds reconstructed particles. The single particle level physics objects, like the leptons, the photons, and the kaons, are identified directly. Subtracting the initial 4-momentum of the system with the accumulated four-momentum of every final state particle leads to the reconstruction of the missing energy and momentum. High level re-

construction algorithms are applied to reconstruct compound physics objects such as the converted photons, the K_s s, the τ leptons, and the jets. Once the jets are identified, the jet flavor tagging algorithm, jet charge measurement algorithm are applied accordingly. The physics observables could then be constructed via the algebraic combinations of the kinematic variables of these physics objects.

10.2.2.1 Tracking

The CEPC software uses the entire tracking module from the ilcsoft, which is proved to have excellent performance. To reserve the flexibility of tracking geometry modification, a dedicated CEPC tracking algorithm is under developing.

10.2.2.2 PFA

The Particle Flow algorithm, Arbor [?] [?], has been optimized for the APODIS detector concept. Arbor is composed of clustering module and a matching module. The clustering module reads the calorimeter hits and builds the calorimeter clusters. It reconstructs each shower cluster into a tree topology. At a high granularity calorimeter, it could efficiently separate nearby particle showers and reconstruct the shower inner structure. Meanwhile, it maintains a high efficiency in collecting the shower hits/energy, which is appreciated by the neutral particle energy reconstruction.

The matching module identifies the calorimeter clusters induced by charged particles (charged clusters), combines these clusters with tracks, and builds charged reconstructed particles. The remaining clusters are reconstructed into photons, neutral hadrons, and fragments (mainly from charged clusters). The final state particles are therefore reconstructed.

Dedicated lepton identification (LICH [?]) and photon identification algorithms have been developed and integrated into Arbor. Arbor reads in calorimeter hits and the reconstructed tracks, and output all the reconstructed particles with particle identification information. Therefore, Arbor algorithm serves as the core of the CEPC reconstruction. The performance will be presented in section 10.3.

10.2.2.3 High level reconstruction

Coral, a simple algorithm that targets at a general simple composed object finder, is in the early developing and testing phase. Coral target at a high efficiency reconstruction of converted photon, π_0 , K_s , *etc.*

A dedicated tau finder has been developed, see [?]. Details will be giving in section 10.3.

In terms of the jet reconstruction and jet flavor tagging, the Fastjet [?] package has been used in CEPC software. CEPC software uses the flavor tagging algorithm, LCFI-Plus [?], from the ilcsoft.

10.3 Performance at the Physics Object level

This section presents the reconstruction performance of core physics objects at the CEPC: the leptons, the photons, the kaons, and the jets. A comprehensive diagnosis on the low level objects(tracks and clusters) reconstruction performance is also reported.

10.3.1 Tracks

The APODIS tracking system is composed of a TPC main tracker and a silicon tracking system. These two subsystems play complementary roles. The TPC has more than 200 radial layers, and has a high efficiency track finding performance. The silicon devices provide high precision spatial point measurements. Comparing to a standalone TPC, this combination improves significantly the tracking momentum resolution, especially for high energy tracks. In addition, the silicon tracking system includes a forward tracker that increases significantly the solid angle coverage of the tracker.

This section presents the tracking performance on two samples: a single muon particle gun sample and a $Z \rightarrow \tau^+\tau^-$ sample corresponding to the CEPC Z pole operation. The particle gun sample describes the tracking efficiency and accuracies for isolated tracks. And the $Z \rightarrow \tau^+\tau^-$, with one of the τ lepton decays into 3 prong final states, provides a critical test for the separation performance of nearby tracks. These samples are reconstructed with Clupatra, the tracking module at the ilcsoft [?].

The single muon particle gun sample has a total statistic of 10 million, and covers a momentum range from 0.1 GeV to 100 GeV. Fig. 10.2 shows the extracted differential efficiency and resolution on the polar angle and the particle energy. Clearly, once the energy is larger than 0.5 GeV, and the track is within tracker fiducial region of $|\cos(\theta)| < 0.985$, the tracking efficiency converges 100%. While the relative accuracy of transverse momentum resolution reaches per mille level for the energy range of 10 - 100 GeV.

The CEPC Z pole operation provides very clean $Z \rightarrow \tau^+\tau^-$ signal. About 10% of the τ lepton decays into 3-prong final states. A typical event is displayed in Fig. 10.3. Since the τ is highly boosted at the $Z \rightarrow \tau^+\tau^-$ events, the three charged particles decayed from the same τ lepton can be confined in a very narrow cone. Thus, these physics events pose stringent requirement on the nearby track reconstruction performance.

A dedicated $Z \rightarrow \tau^+\tau^-$ sample, with one τ decays into $2\nu\mu$ and the other into three charged pions and one neutrino. Defining the successful reconstruction efficiency as the probability of reconstructing three target tracks in these events with three visible pions in the events. The reconstruction efficiency is close to 100%.

To conclude, the tracking system at the APODIS provides a high efficiency, and high accuracy reconstruction of the track. In the tracker fiducial angle ($|\cos(\theta)| < 0.985$), the reconstruction efficiency reaches 100% for tracks with momentum larger than 0.5 GeV. An overall reconstruction efficiency close to 100% has been achieved for $\tau \rightarrow 3\pi\nu$ sample. A dedicated analysis shows the charge misidentification rate is smaller than 10^{-4} , mostly concentrated at very forward region [?]. This tracking performance provides a solid starting point for the Particle Flow reconstruction at the APODIS.

10.3.2 Clusters

Fig. 10.4 shows a reconstructed calorimeter shower of a 20 GeV K_L^0 particle at the high granularity calorimeter, where the readout density is roughly 1 channel/cm³. The reconstructed tree branches are demonstrated with different colors. Therefore the trajectory length of charged shower particle can be reconstructed. Fig. 10.5 compares the reconstructed trajectory length with MC truth, the red distribution is the MC truth level trajectory length of charged particles generated inside 40 GeV π showers; the green one is corresponding to the trajectory of the electron and the positron generated in the showers;

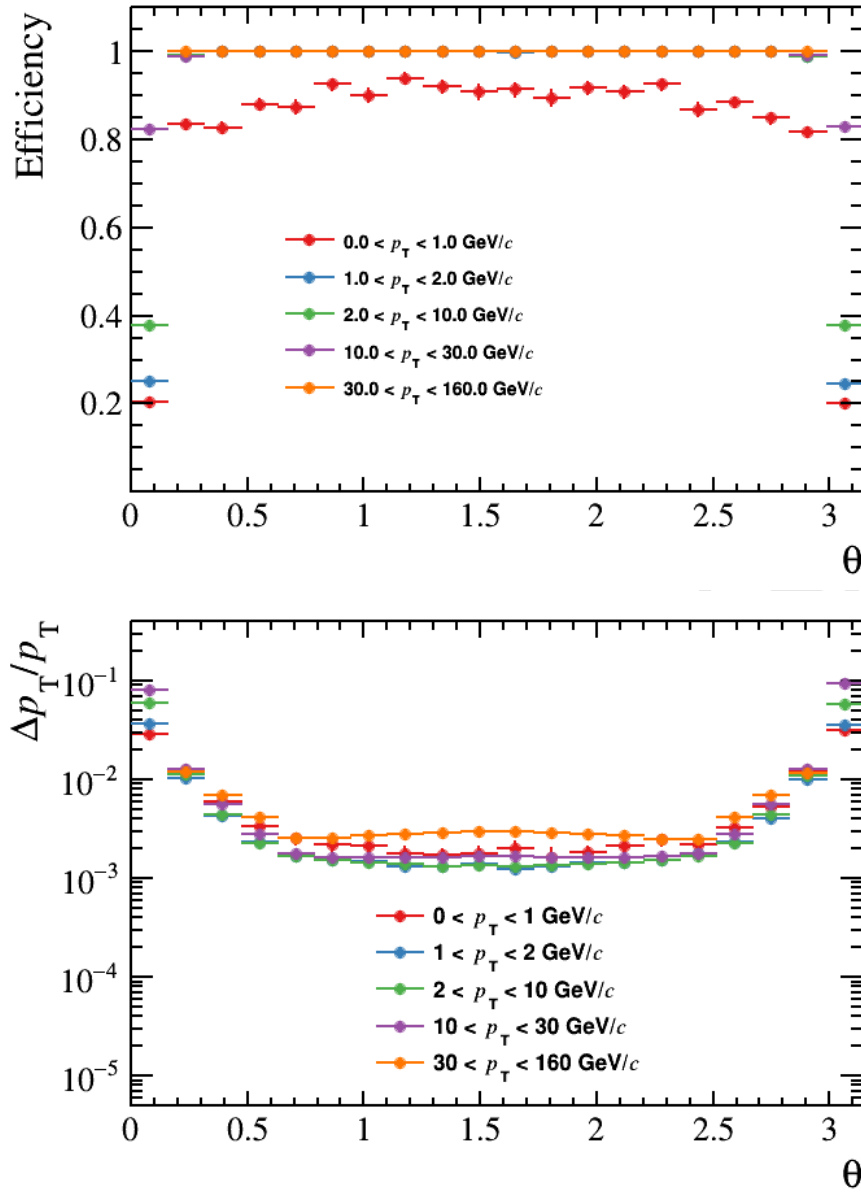

Figure 10.2: Single particle reconstruction efficiency (up plot) and resolution (lower plot) as a function of the track momentum and track polar angle.

while the blue is the trajectory length reconstructed by Arbor. Good agreement between the reconstruction and MC truth is found at sufficient trajectory length.

Arbor can also be characterized by the energy collection performance at single neutral particle and the separation performance at bi-particle samples. Typically, Arbor reaches an energy collection efficiency higher than 99% for photons with energy higher than 5 GeV at the APODIS geometry. Higher hit collection efficiency usually leads to a better energy resolution but also increases the chance of confusions, i.e., the wrong clustering of calorimeter hits.

Excellent separation performance is crucial for the jet energy reconstruction, the π^0 reconstruction, and the measurement with τ final states. This performance can be char-

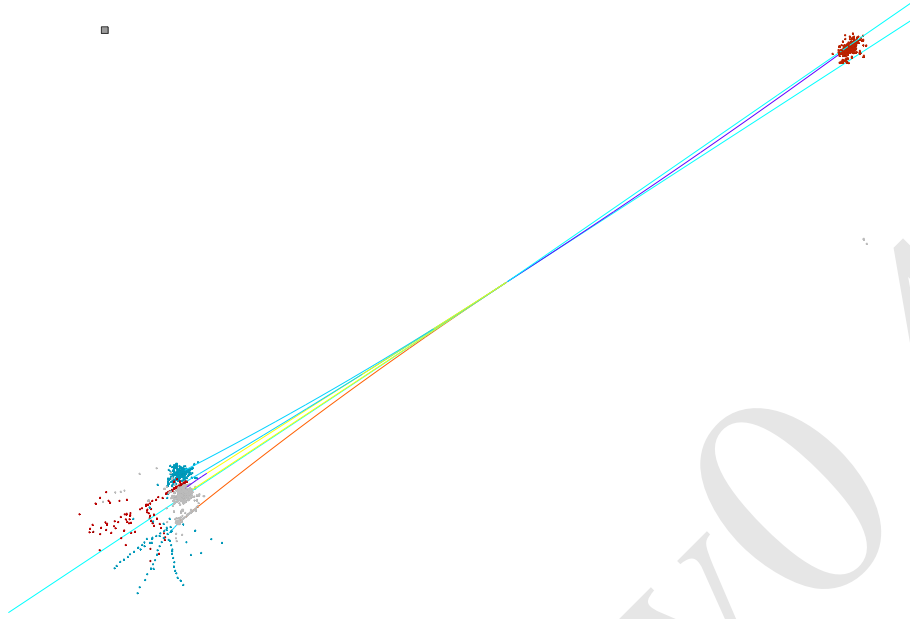

Figure 10.3: A simulated $Z \rightarrow \tau^+\tau^-$ event at CEPC Z pole operation. The left hand side τ lepton decays into 3 charged tracks, and 1 FSR photon. Through leptonic decay, the right handed one decays into an electron and two neutrinos.

ECAL cell size	Critical distance for separation
1 mm	4 mm
5 mm	9 mm
10 mm	16 mm

Table 10.1: Arbor critical separation distance at di-photon sample with different ECAL cell size.

acterized via the reconstruction efficiency of di-photon samples, where two photons with the same energy are shot in parallel at different positions, see Fig. 10.6. According to the distribution of π^0 energy at $Z \rightarrow \tau^+\tau^-$ events at CEPC Z pole operation, we set the photon energy to 5 GeV.

The reconstruction efficiency is defined as the probability of successfully reconstructed two photons with anticipated energy (each candidate is required to have an energy within 1/3 to 2/3 of the total induced energy). The efficiency curve naturally exhibits an S-curve dependency on the distance between the photon impact positions, see Fig. 10.7. The distance at which 50% of the events are successfully reconstructed is referred to as the critical distance, which depends on the ECAL transverse cell size. At the cell size smaller than the Moliere radius, the critical distance is roughly 2 times the cell size, see Table. 10.1.

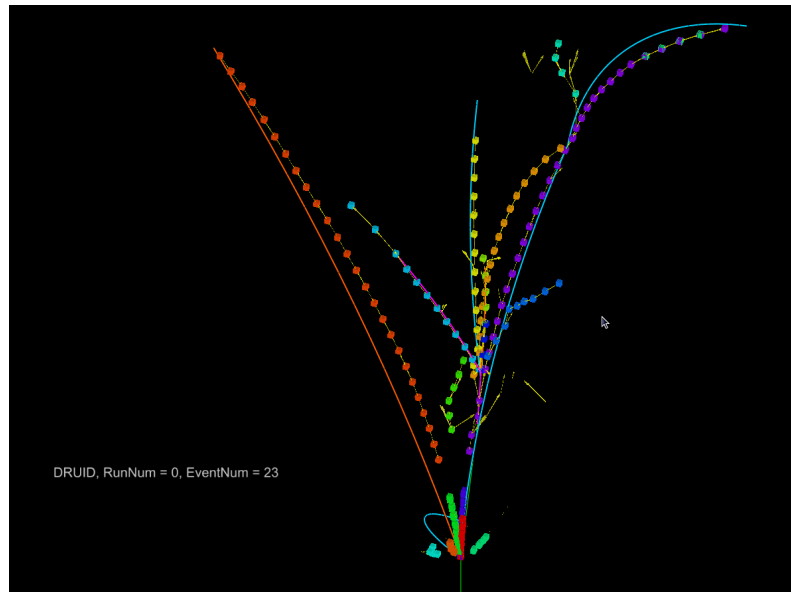

Figure 10.4: K_L shower reconstructed by the Arbor algorithm, the branches — the calorimeter hit clusters — are corresponding to the trajectories of charged particles generated in the shower cascade.

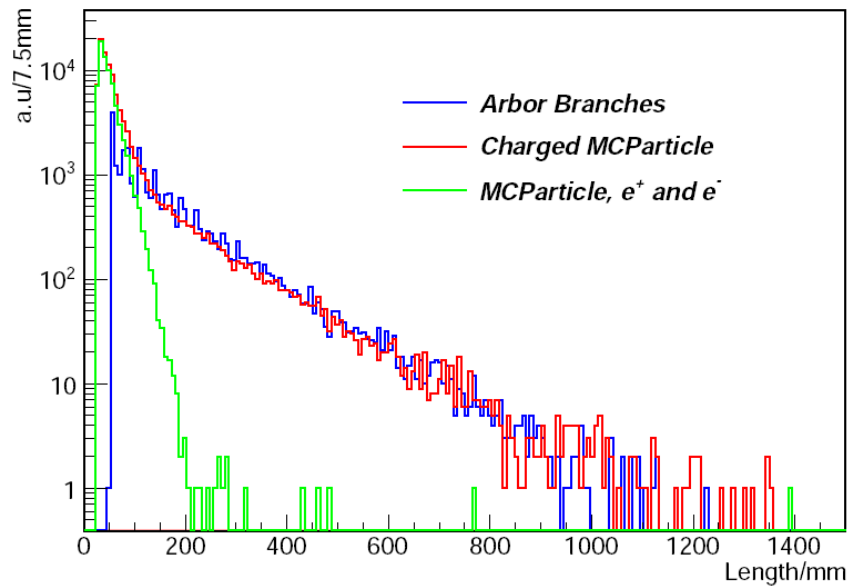

Figure 10.5: Proof of Principle: reconstructed and MC truth particle trajectory length at 40 GeV π showers.

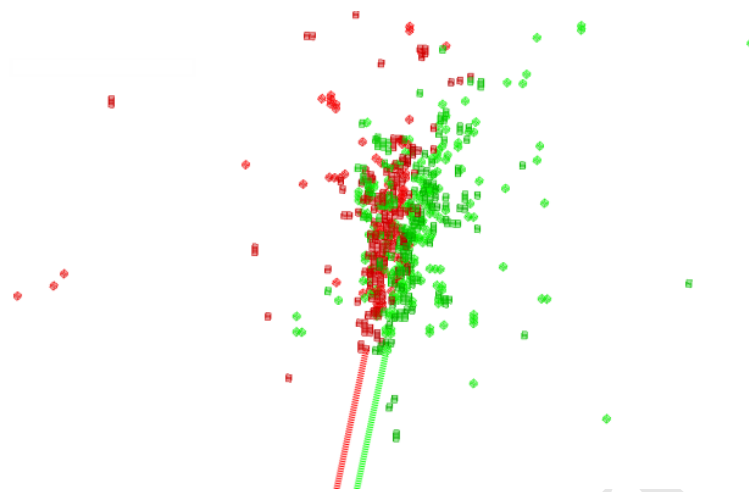

Figure 10.6: A reconstructed di-photon event at Si-W ECAL with 1 mm cell size. Each photon has an energy of 5 GeV, and their impact points are separated by 4 mm.

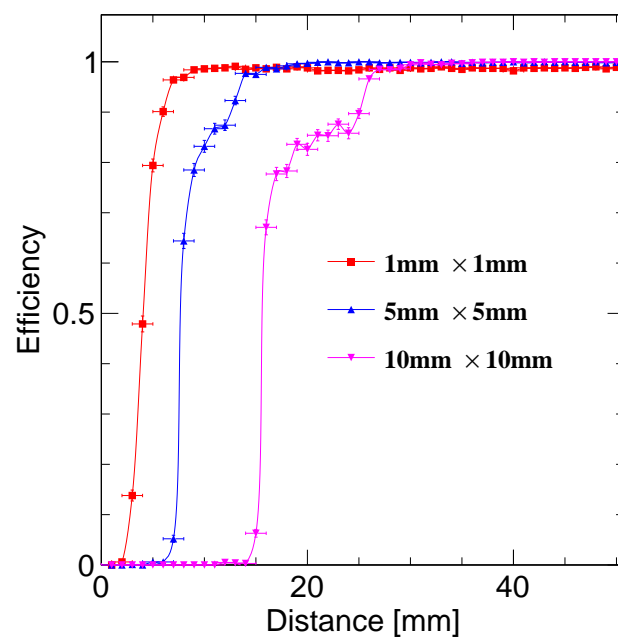

Figure 10.7: Reconstruction efficiency of the di-photon events at different ECAL cell sizes. The X-axis represents the distance between photon impact points.

10.3.3 Leptons

The lepton identification is of key importance to the CEPC Higgs program. First of all, about 7% Higgs boson events at the CEPC are generated together with a pair of leptons. Those events are the golden signals for the Higgs recoil analysis, which is the anchor for the absolute Higgs measurements. A significant fraction of the Higgs boson decays, directly or via cascade, into final states with leptons. 0.02% of SM Higgs decays into muons; the leptons serve as the essentially candles of identification of $H \rightarrow WW/ZZ \rightarrow$ leptonic/semi-leptonic final states. In addition, a significant fraction of Higgs- \rightarrow bb/cc events generate leptons in their decay cascade.

The PFA oriented detector, especially its calorimeter system, could provide enormous information for the lepton identification. In the CEPC v_4 geometry, a high-energy electron/positron/hadrons is likely to induce thousands of hits in the calorimeter with typical spatial configurations. Using the benchmark calorimeter geometry, the shower fractal dimension could be extracted [?]. In addition, the dE/dx measured by the TPC could efficiently separate electron/positrons from muon and hadrons, at track energy less than 10 GeV.

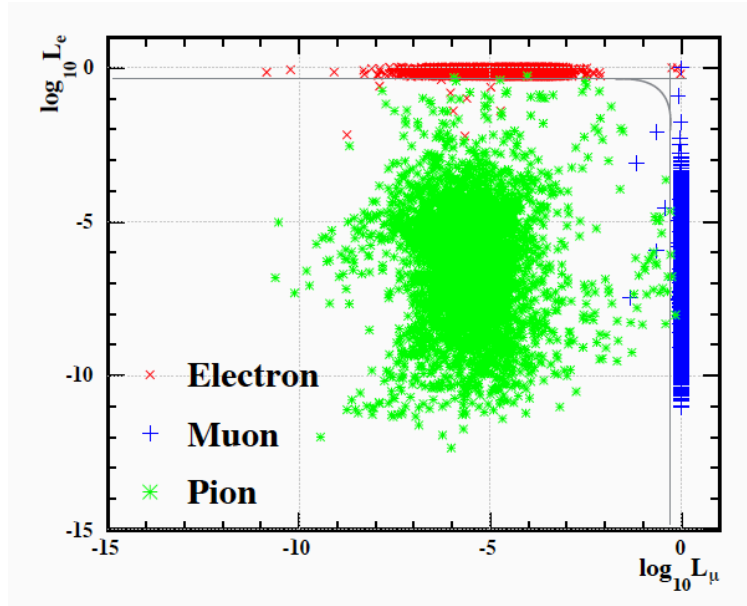

Figure 10.8: The distribution of charged particles in the phase space of calculated lepton likelihoods.

A dedicated Lepton identification algorithm for the detectors using high granularity calorimeter, LICH [?], has been developed. LICH extract more than 20 distinguish variables from the detector and combine these information into lepton-likelihood via MVA method. The performance of LICH have been scanned over a large range of the granularity for both ECAL and HCAL, while the performance is stable for particles with energy larger than 2 GeV.

At APODIS geometry, applied on isolated charged particle candidate with energy larger than 2 GeV, lepton identification efficiency better than 99.5% could be achieved with a mis-identification rate from hadrons is controlled to be smaller than 1%. This mis-identification is mainly induced by the irreducible background rate from pion decay (to muons) and highly electro-magnetic like pion clusters (via the pion0 generated from the

pion-nuclear interactions). Not surprisingly, this performance is significantly better than that at LHC and LEP [?][?].

In the actual physics event, the lepton identification performance will be limited by the separation power of the detector. Using fully reconstructed llH events, we found the efficiency of successfully identify two leptons with opposite charge reaches 97-98%, In other word, less than 1% of the objective leptons in the llH events will potentially be mis-identified due to the overlapping of their cluster to the nearby showers. This result is consistent with the separation power of APODIS.

In terms of the Higgs signal at the CEPC, the tracking and the lepton identification performance can be characterized by the recoil mass distribution of l^+l^-H events and the invariant mass distribution of the $H \rightarrow \mu^+\mu^-$ events. These distributions are presented below.

10.3.3.1 Higgs recoil mass distribution at l^+l^-H events

The Higgs recoil mass distributions at the l^+l^-H events are the most characteristic distributions of the electron positron Higgs factories. Since the initial 4-momentum is precisely known at the electron positron collider, and the pair of leptons (mostly generated from Z decay but also a few from the Z fusion events) could be precisely reconstructed, the recoil mass of Higgs boson could be calculated. Therefore, without any direct measurement on the Higgs boson decay final states, the Higgs signal could be identified by the characteristic recoil mass peak, whose position indicates the mass of Higgs boson and the total number of signal events is proportional to g_{HZZ}^2 .

This distribution leads to a precise determination of the both Higgs boson mass and g_{HZZ} . The measurement of the Higgs boson mass is of strong physics interest itself. More importantly, the measurement of g_{HZZ} is unique at the electron positron Higgs factory. It anchors all the absolute Higgs boson measurements at the electron positron collider, and is highly complementary to the Higgs measurements operated at LHC and HL-LHC.

The di-muon recoil mass distribution is shown in Fig. 10.9. This distribution has a long high mass tail, induced by many radiation effects (the beamstrahlung, the bremsstrahlung, the final state radiation, and most importantly, the initial state radiation). The width of the peak distribution is determined by the intrinsic track momentum resolution and the beam energy uncertainty, both of which are at per mille level at the CEPC.

In terms of the detector response, the recoil mass measurements require a high efficiency, high precision tracking system, good lepton identification performance.

10.3.3.2 The di lepton invariant mass distribution of $vvH, H \rightarrow \mu^+\mu^-$ events

CEPC could generate roughly 200 $H \rightarrow \mu^+\mu^-$ events. Thanks to the high precision tracking performance, the signal strength could be measured to a relative accuracy of 15% at the CEPC. The reconstructed di muon invariant mass distribution is shown in Fig. 10.10.

Fig. 10.10 exhibits a low mass tail, induced mainly by the bremsstrahlung and FSR effects of the charged muon. In addition, the Higgs mass peak has a bias of 100 MeV, mainly induced from a bias in the dEdx estimation in current simulation module.

10.3.4 Kaon Identification

Successful identification of the charged kaons is crucial for the flavor physics, and is highly appreciated in the determination of jet flavor and jet charge. According to the

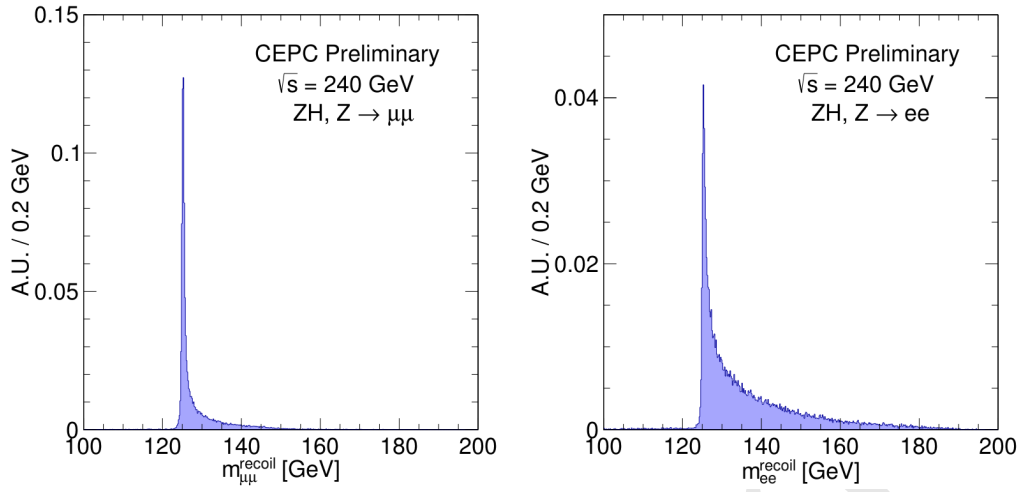

Figure 10.9: Recoil mass distribution of the $\mu^+\mu^-H$ and e^+e^-H events. Normalized to unit area.

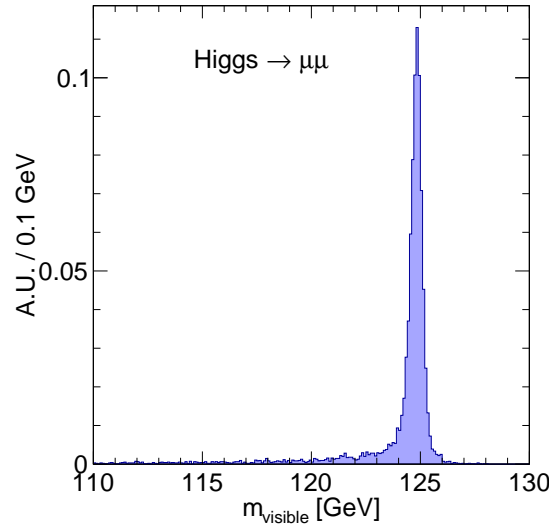

Figure 10.10: The reconstructed Higgs invariant mass of $H \rightarrow \mu^+\mu^-$ events at the CEPC v_1 detector geometry. 8k events, normalized to unit area.

Bethe-Bloch equation, in the realistic energy range and at the same track momenta, the dEdx of pions is larger than that of kaons by roughly 10%. In other word, if the dEdx resolution could be measured to a relative accuracy better than 5%, the dEdx could leads to an efficient π - K separation.

The APODIS is equipped with a large TPC main tracker. Depending on the readout hardware performance, the dE/dx resolution leads to 2-4 σ π - K separation for 2-20 GeV charged tracks. See the left plot of Fig. 10.11. The upper boundary is the ideal separation predicted by the Geant4 simulation; while the lower boundary includes a 50% degrading with respect to the MCTruth, and is regarded as the conservative scenario. (A survey of the performance at previous experiments shows the degrading varies from 15% to 50%). The dE/dx separation between other charged particles is also demonstrated.

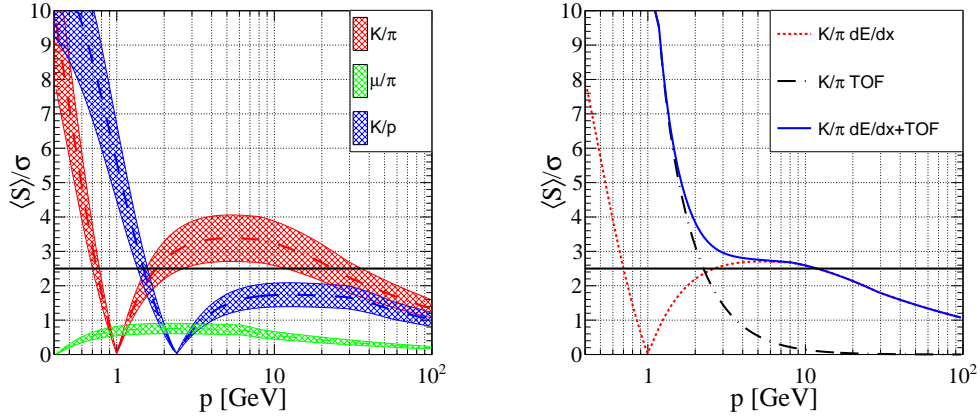

Figure 10.11: π - K separation performance at PICADOR detector. Left plot, dE/dx separation between different charged particles at 0.4 ~ 100 GeV track momentum. Right plot, the separation power using both dE/dx and ToF information.

The difference between the dE/dx of pions and kaons vanishes at 1 GeV track momentum. Meanwhile, a significant portion of charged particle has energy smaller than 2 GeV at the CEPC. To separation these low energy charged particles, a Time of Flight (ToF) measurement with 50 ps time resolution is proposed. The ToF information could be measured by the ECAL, with a few layers equipped with the Time sensitive ASICs. Using both ToF and dE/dx information, a separation better than 2σ could be achieved for tracks with momenta smaller than 20 GeV in the conservative scenario.

Considering the CEPC inclusive $Z \rightarrow q\bar{q}$ sample and integrate over the full polar angle and the momenta range of 2 ~ 20 GeV, an over all charged kaon identification reaches an efficiency and purity of 91%/94% at the APODIS in the conservative scenario. If the dE/dx measurements could be improved to 3.6% (20% degrading comparing to the MCTruth), the efficiency and purity of charged Kaon identification could be improved to better than 95% [?].

10.3.5 Photons

Successful photon reconstruction is crucial for the jet energy reconstruction, the $Br(H \rightarrow \gamma\gamma)$ measurement, and the physics measurements with τ leptons. Since the separation performance has been demonstrated in the section ??, this section is devoted to the reconstruction efficiency and the energy measurement of single photon.

The photon reconstruction is sensitive to the tracker material and the calorimeter geometry defects. To quantify their impact, a simplified, defect-free silicon tungsten ECAL geometry is implemented. This simplified geometry uses cylindrical barrel layer and its endcaps are directly attached to the barrel, forming a closed cylinder. The simplified geometry takes its inner radius and length of 1800 mm and 4700 mm (similar to the APODIS parameters). Along the longitudinal direction, the simplified ECAL is divided into 30 identical layers, each consist of one 2.8 mm tungsten absorber layer, one 0.5 mm silicon sensor layer and a 2 mm thick PCB layer. The thickness of the tungsten absorber and silicon sensor is adjustable, with which a dedicated optimization study has been performed and the ECAL geometry of APODIS is determined [?].

The reconstruction performance of a single photon is characterized by the finding efficiency and the energy collection efficiency. The finding efficiency is the chance that at least one ECAL cluster is reconstructed for one event with one photon incident into the detector fiducial region. The energy collection efficiency is defined as the accumulated hit energy in the photon cluster divided by that in all the hits.

At the simplified ECAL geometry, the finding efficiency reaches 100% for photons with energy larger than 500 MeV. The finding efficiency decreases to 85% once the photon energy is reduced to 100 MeV. The energy collection efficiency is better than 99% when the photon energy ranges from 1 GeV to 175 GeV. When the photon energy is less than 1 GeV, the energy collection efficiency degrades, i.e., the average energy collection efficiency decreases to 75% for 100 MeV photons. Since the simplified ECAL has no material before the calorimeter, it maintains high efficiencies even for low energy photons.

The single photon energy resolution of the simplified 30-layer ECAL is displayed as the black curve in Figure ??, which is consistent with the test beam result of ILD ECAL prototype [?]. Reducing the number of layers (by enlarging the tungsten absorber thickness at each layer, but keep the) means fewer read-out channels, which leads to lower construction cost and power consumption. Keeping the total absorber thickness at the optimized value of 84 mm, reducing the readout layer numbers and maintaining the local sensor thickness, the ECAL energy resolution degrades as the sensor-absorber ratio decreases. Compared with 30 layers option, the energy resolution degrades by 11% at 25 layers and 26% at 20 layers.

The degradation of photon energy resolution by reducing the number of channels could be compensated by using thicker silicon sensor. We found that the energy resolution of ECAL at 20 layers with 1.5 mm thick silicon wafer, 25 layers with 1 mm thick wafer and the baseline geometry (30 layers with 0.5 mm thick wafer) has the same energy resolution. This conclusion is confirmed by the analyses at the Higgs physics benchmarks of $H \rightarrow \gamma\gamma$ and $H \rightarrow gg$ [?].

To conclude, the simplified geometry has an ideal efficiency of photon reconstruction and a consistent energy resolution w.r.t the CALICE ECAL prototype. We found that using thicker silicon wafer, the ECAL number of layers thus its construction cost and power consumption could be significantly reduced. Therefore, we strongly encourage the feasibility study of the thicker silicon sensor wafers.

At the APODIS detector, the total amount of material before the calorimeter is roughly 5-10% of one radiation length. This material will reduce the reconstruction efficiency for the low energy photons, and caused 5-10% of high energy photons to convert into electron-positron pairs. The geometry defects, such as the cracks between the ECAL modules, staves, and the dead zone between the ECAL barrel and endcaps, induces geometry based bias for the photon energy measurements and need to be corrected. The overall photon reconstruction could be benchmarked with the Higgs mass resolution at $H \rightarrow \gamma\gamma$ event at both simplified and the APODIS geometry, which will be discussed in section 10.3.5.1.

10.3.5.1 The di photon invariant mass distribution of $vvH, H \rightarrow \gamma\gamma$ events

The SM Higgs boson has 0.2% chance to decay into a pair of photons. Since photons could be easily identified, this channel becomes one of the Higgs discovery channels at the LHC. At the CEPC, this channel serves as a benchmark to characterize the ECAL performance.

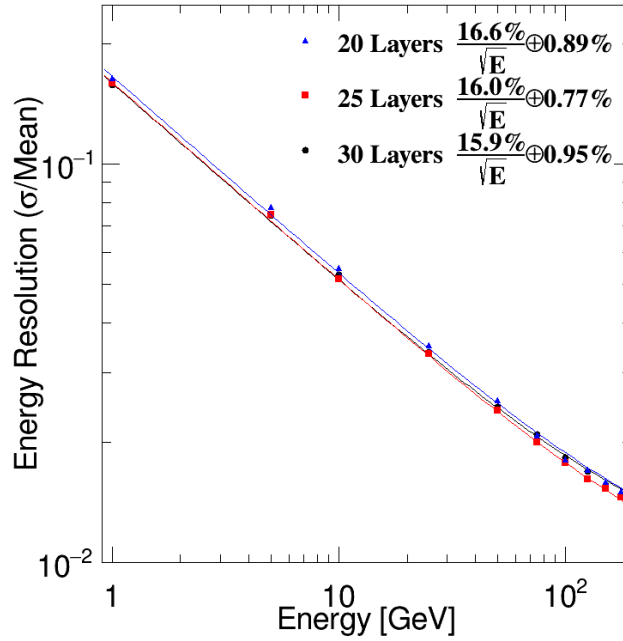

Figure 10.12: Energy resolution with fewer layers and thicker silicon wafers (20 layers with 1.5 mm silicon wafer and 25 layers with 1 mm silicon wafer), compared to 30 layers and 0.5 mm thick silicon wafer.

Using the reconstructed $vvH, H \rightarrow \gamma\gamma$ sample and calculate the invariant mass of two most energetic photon candidates, we acquire the objective distributions at both simplified ECAL geometry and at APODIS, see Fig. 10.13 and ??.

At the simplified ECAL geometry, a clean Gaussian distribution is identified with a tiny low mass tail. The low mass tail is induced by the artificial splitting of the photon cluster. A relative mass resolution of 1.7% is achieved, which agrees with the intrinsic electromagnetic energy resolution measured at the CALICE Si-W ECAL prototype test beam experiments [?].

Comparing to the simplified geometry, the relative resolution of the Higgs mass at APODIS degrades significantly. A preliminary geometry based correction algorithm has been developed, which scales the energy of EM clusters located at the geometry cracks. This distribution could be fit to a core Gaussian center and a wider Gaussian with a lower mean value. The core gaussian exhibits a mass resolution of 1.9%, while the low-mass wider gaussian is caused by the fact that the correction algorithm is only optimized. The average mass resolution (taking a weighted average of both Gaussian) is then 2.6%. The latter can be improved with much dedicated correction algorithm.

To summarize, our simulation predicts the Higgs mass resolution at two-photon final state reaches 1.6-2.6% level at the CEPC. This result is consistent with the CALICE prototype test beam result. The reconstruction of converted photons and the correction of the geometry defects at any realistic detector geometry is crucial for the photon reconstruction.

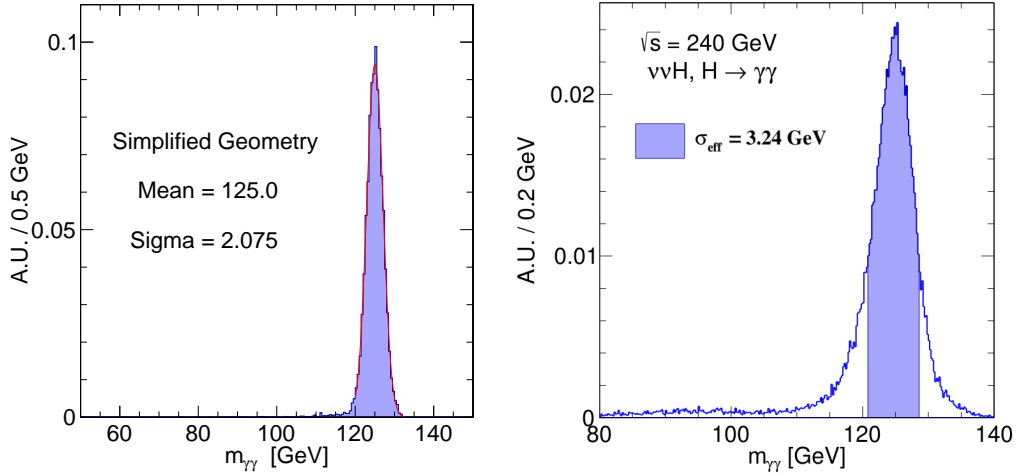

Figure 10.13: The reconstructed Higgs invariant mass of $H \rightarrow \gamma\gamma$ events at the simplified detector geometry (Left) and at APODIS (Right). 10k and 6k events are reconstructed correspondingly. Each distribution is normalized to unit area.

10.3.6 Taus

The particle flow oriented design provides good separation of final state particles, and high efficiency reconstruction of the charged particles and photons. In addition, through the track impact parameter reconstruction, the high precision vertex system could efficiently separate the prompt tracks from those generated at the τ decay. Therefore, the CEPC baseline geometry ensures a good performance of the τ reconstruction.

Through the physics analysis of $H \rightarrow \tau^+\tau^-$ branching ratio measurements [?], two independent τ reconstruction algorithms have been developed, corresponding to the physics events with/without jets in the final states.

The physics events without jets can be represented by l^+l^-H events. In these events, the prompt lepton pairs are identified using the Z boson invariant mass, while the τ candidates are searched at the remaining particles. The τ candidates are defined as the charged particles isolated from other tracks (potentially has a few nearby photons). Using the charged track and photon multiplicity, and the identified lepton pair, the $l^+l^-H, H \rightarrow \tau^+\tau^-$ events could be identified with an efficiency better than 90%, while the entire SM background is reduced by 5 orders of magnitudes. In fact, the remaining background is mainly the l^+l^-H events, with Higgs decays into WW^* or ZZ^* and then cascades into leptonic final states.

The physics events with jets is represented by qqH events. Using a double size cone based algorithm, the τ candidates are identified. The large cone is used to define the τ isolation, while the small cone verifies on the charged particle/photon multiplicity, and the τ visible mass consistency. At the $qqH, H \rightarrow \tau^+\tau^-$ events, this τ finding algorithm reaches an efficiency and purity better than 70%. More details could be found in section ??.

10.3.7 Jet

Plots on the JES, WZH separation, and the JER to be updated

The jet is fundamental for the CEPC physics program. About 90% of the SM Higgs boson decays into final states with jets (70% directly to di-jet final states; and roughly 20% via decay cascade from the ZZ^* , WW^*), while 70% of W and Z bosons decay into di-jet final states. Roughly 60% of the jet energy is carried by the charged particles, and the Particle Flow could improve significantly the precision of jet energy measurement with respect to the calorimeter based reconstruction.

In the Particle Flow reconstruction, the jet candidates are constructed from the reconstructed final state particles via the jet clustering algorithms. The ambiguity from the jet clustering is significant and usually dominates the uncertainty, especially for these events with more than two final state jets such as the measurement of $g(Hb\bar{b})$, $g(Hc\bar{c})$, and $g(Hgg)$ via $ZH \rightarrow 4jet$ events.

To characterize the jet reconstruction performance, a two-stage evaluation has been applied at the CEPC studies. The first stage is the Boson Mass Resolution (BMR) analysis designed to avoid the complexity induced by the jet clustering. The second is the individual jet response analysis, which requests the jet clustering.

The Boson Mass Resolution analysis is applied to physics events with two final state jets decayed mostly from one intermediate gauge boson, including

- 1, $\nu\tilde{\nu}q\bar{q}$ events via the ZZ intermediate state;
- 2, $lvq\bar{q}$ events via mostly WW intermediate state;
- 3, $\nu\tilde{\nu}H$ events with $H \rightarrow b\bar{b}, c\bar{c},$ or gg .

In these processes, besides the jet final state particles, the other particles are either invisible or could be easily identified. The invariant mass of all the final state particles decayed from a massive boson can therefore be reconstructed. Therefore, disentangled from the jet clustering algorithm, the BMR evaluates the jet reconstruction. Meanwhile, the BMR shows immediately how these massive gauge bosons can be separated at jet final state.

Using the jet clustering and matching algorithms, the jet response is also analyzed at each individual jet. The overall response includes the detector resolution, the ambiguous induced by the jet clustering and the mismatching. These effects are physics process dependent and a complete analysis is beyond the scope of this manuscript. In this paper, this analysis is limited to individual jet reconstruction performance at $\nu\tilde{\nu}q\bar{q}$ process.

Corresponding to $5 ab^{-1}$ integrated luminosity at the CEPC, we simulate 1.8 millions $\nu\tilde{\nu}q\bar{q}$, 11 millions $lvq\bar{q}$ and 170 thousands $\nu\tilde{\nu}H, H \rightarrow jj$ events at $\sqrt{s} = 250 GeV$ with the CEPC v_1 geometry. All these samples are reconstructed with Arbor. Fig. 10.14 shows the inclusive reconstructed boson mass distributions normalized to unit area. These distributions are well separated, each exhibits a peak at the expected boson mass. These mass distributions are all asymmetric for different reasons. At the low mass side, the green distribution, corresponding to $\nu\tilde{\nu}H, H \rightarrow jj$ events, has a long tail. This tail is mainly stemmed from the neutrinos generated in the heavy jets fragments (most of the $H \rightarrow jj$ events are $H \rightarrow b\bar{b}$ events). The heavy jet components are also responsible for the low mass tail in the other two distributions. Because W boson hardly decays into b-jets, the low mass tail of $lvq\bar{q}$ sample is much less significant. The Breit-Wigner width of massive gauge bosons and the phase space effects also contribute to the long tails at the

$lvq\bar{q}$ and the $\nu\bar{\nu}q\bar{q}$ samples. The high mass tail induced by ISR photon(s) is observed in each distribution.

To decouple the detector response from these physics effects, a standard cleaning procedure is designed:

- 1, The jets are generated from light flavor quarks (u, d) or gluons.
- 2, Acceptance: the partons should have a significant angle to the beam pipe: $|\cos(\theta)| < 0.85$.
- 3, ISR veto: there is no energetic visible final state ISR photon: the accumulated scalar transverse momentum of the ISR photons should be smaller than 1 GeV.
- 4, Neutrino veto: there is no energetic neutrino generated from the jet fragmentation cascade: the accumulated scalar transverse momentum of the jet neutrinos should be smaller than 1 GeV.

This event selection clearly leads to narrow boson mass distribution and better separation, see Fig. ??.

After this event selection, the mass distributions are much symmetric. The Higgs boson mass could be simply fit to a Gaussian, while the other two distributions include the non-negligible intrinsic widths. The efficiency of this event selection depends on the decay branching ratio (condition 1), differential cross section (condition 2), the radiation behavior (condition 3) and jet fragmentation (condition 4). As in the $\nu\bar{\nu}H, H \rightarrow gg$ sample, this event selection has an overall efficiency of 65% (75%/94%/94% for the 2nd/3rd/4th condition, respectively). The relative mass resolution of the Higgs mass is then 3.8%, providing a quantitative reference for the BMR.

It should be remarked that both lepton identification and jet flavor tagging information are available in current reconstruction. Combining these information enhances the distinguishing power on different physics processes.

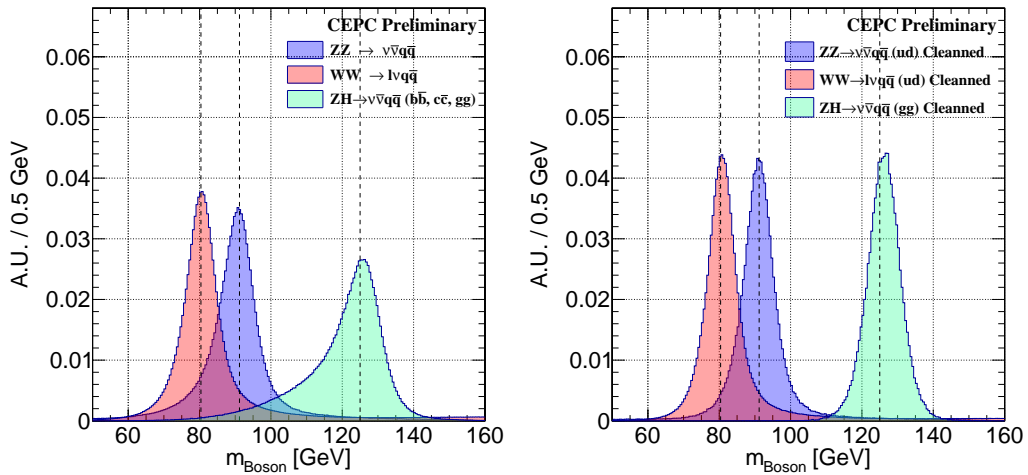

Figure 10.14: Reconstructed boson masses of the inclusive (Left) and cleaned (Right) $lvq\bar{q}$ (red), $\nu\bar{\nu}q\bar{q}$ (blue) and $\nu\bar{\nu}H, H \rightarrow jj$ samples (green).

The calibration process plays an important role in measuring the jet energy. Technically, Arbor was calibrated via two steps, the single particle level calibration, and the data-driven calibration. The single particle calibration is to figure out the global ECAL/HCAL calibration constants according to the comparison between the reconstructed neutral particle energy and the truth. The ECAL calibration constant is derived from photon samples while the HCAL calibration constant at K_L^0 samples. Due to the Particle Flow double counting, i.e. the fragments of charged particle showers are misidentified as neutral particles, the single particle calibration leads to typically 1% overestimation on the boson mass. The data-driven calibration is to scale all the reconstructed boson masses according to the W mass peak exhibited in the $l\nu q\bar{q}$ events, the leading physics processes of the above three. This simple calibration simultaneously scales the three boson mass peak positions to the expected positions. To fully appreciate the enormous productivity of massive bosons at the CEPC, sophisticated calibration methods must be developed and validated for the real experiments, i.e. control and corrections of differential dependences, in-situ calibrations, detector homogeneity monitoring and control, *etc.*

The reconstruction performance of individual jet is explored via the same $\nu\bar{\nu}q\bar{q}$ sample. Using ee-anti-kt algorithm (a.k.a Durham algorithm [?]), all the reconstructed particles are forced into two jets (recojets). The same jet-clustering algorithm is applied to the visible final state particles at the MC truth level, forming the generator level jets (genjets). Using a matching algorithm that minimizes the angular difference, the jet reconstruction performance is characterized by the difference between the 4-momentum of the initial quarks, the genjets, and the recojets. The difference between the quarks and the genjets is mainly coming from the fragmentation and the jet clustering processes, while the difference between the genjets and the recojets is induced by the jet clustering, matching, and the detector response. A dedicated analysis shows that, even at this simple di-jet process, the uncertainty induced by the jet clustering and matching can be as significant as those from the detector response [?].

These two reconstructed jets are classified into leading/sub-leading jets according to their energy. The relative energy difference between genjet and recojet is then fit with a double-sided crystal ball function. The exponential tails are mainly induced by the jet clustering algorithm, the matching performance, and the detector acceptance. The Gaussian core then describes the detector resolution, therefore we define its mean value as the Jet Energy Scale (JES) and its relative width as the Jet Energy Resolution (JER).

Fig. 10.15 shows the JES at different jet directions. The JES is flat along the azimuth angle. Along the polar angle, the JES increases significantly for the leading jets in the overlap part between the endcap and the barrel. The JES is also larger in the endcap than in the barrel. These patterns are correlated with the Particle Flow confusions, especially the artificial splitting of the charged clusters. Not surprisingly, the leading jets have a systematically higher JES comparing to the sub-leading one. Without any corrections, the entire amplitude of the JES is controlled to 1% level, which is significantly better than that of LHC even after the correction [?].

The jet energy resolution (JER) at different jet transverse momenta is displayed in Fig. 10.16. The overall JER takes a value between 6% (at $P_t < 20$ GeV) to 3% (at $P_t > 100$ GeV). The leading jets usually has a slightly better JER comparing to the sub-leading ones. Taking the performance of the CMS detector as a reference, the JER at the CEPC reference detector is 2-4 times better at the same P_t range [?].

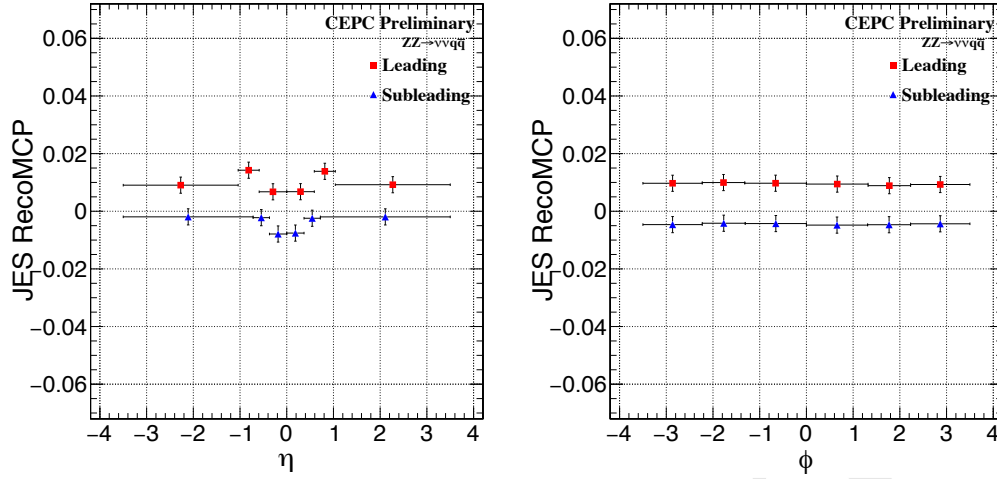

Figure 10.15: Jet energy scale at different jet directions.

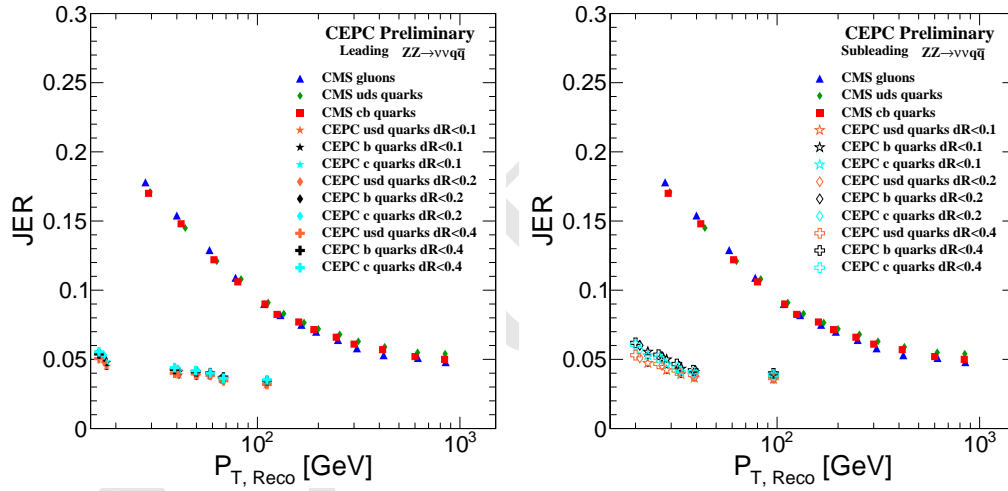

Figure 10.16: The jet energy resolution for leading (upper) and sub-leading jets (lower), as a function of the jet transverse momenta. The performance at the CMS [?] has been overlapped for comparison.

To conclude, the jet energy response has been analyzed at the BMR level and at the individual jet level. For physics events with only two jets, the boson mass could be measured to a relative accuracy better than 4% at CEPC v_1 using a standard event selection. This resolution ensures significant separation between the W boson, the Z boson, and the Higgs boson. At individual jets, the JES is controlled to 1% level and the JER of 3% to 6%, both are significantly better than the LHC detector performances. This superior performance is based on the clean electron-positron collision environment, the PFA oriented detector design and reconstruction. It is highly appreciated for the CEPC physics program, i.e. the measurements of W boson mass at the CEPC Higgs operation. It should also be emphasized that the jet-clustering algorithm has a strong and even dominant impact on the physics measurements with multiple jets in the final states. Tested at the $\nu\bar{\nu}H, H \rightarrow jj$ events, the APODIS detector model gives the same jet energy resolution.

-	$H \rightarrow bb$	$H \rightarrow cc$	$H \rightarrow gg$
Sample statistic	10k	10k	9.6k
$\epsilon_{ISRveto}$	94%	94%	94%
$\epsilon_{neutrino veto}$	41%	69%	94%
$\epsilon_{acceptance}$	74%	74%	74%
Relative mass resolution	$3.60 \pm 0.07\%$	$3.76 \pm 0.05\%$	$3.69 \pm 0.04\%$

Table 10.2: Statistics, cut efficiencies on the $vvH, H \rightarrow dijet$ samples and the relative mass resolution after the cleaning.

10.3.7.1 Total visible mass distribution of $H \rightarrow bb, cc, gg$ events

The majority of the SM Higgs boson decay into di-jet final states: 58%/3% into a pair of b/c quarks via the direct Yukawa coupling, and 8% into a pair of gluon mainly via top quark loop. These di-jet events could be easily identified using its invariant masses. The jet performance has been intensively discussed in section ??, where the inclusive invariant mass distribution of $vvH, H \rightarrow di - jets$ and a cleaned distribution of $vvH, H \rightarrow gg$ are both presented. In this section, we are going to show all these 6 distributions of $vvH, H \rightarrow bb, cc, gg$ wi/wo cleaning.

These inclusive distributions (Fig. 10.17) clearly exhibit nongaussian, asymmetric patterns. As discussed in section ??, these patterns are induced from visible ISR photons, neutrinos generated in Higgs decay cascade, and the detector acceptance. Applying the corresponding cuts in the standard cleaning procedure (defined in section ??), these patterns disappear, see Fig. ??.

The corresponding efficiencies and statistics are summarized in Table 10.2. For three different decay modes, the neutrino veto condition has different efficiencies, and vetoed more than half of the $H \rightarrow bb$ events. The other two condition have essentially identical efficiencies. After the cleaning, the relative mass resolution for three different decay modes converge to a similar level.

10.3.7.2 Total visible mass distribution of $H \rightarrow WW^*$ and ZZ^* events

The Higgs boson have large couplings to the massive gauge mediator. It has a branching ratio of 21%/3% to decays into a pair of W/Z boson, respectively. Limited by the Higgs mass, only one of the massive gauge boson is on shell. The total visible mass for the $vvH, H \rightarrow WW^*/ZZ^*$ events are shown in Fig. 10.18.

The cascade decay of $H \rightarrow ZZ^* \rightarrow 4l$ is the other Higgs discovery channel at the LHC, as multiple leptons is a clean signature. At the CEPC, combining the $Br(H \rightarrow ZZ^*)$ measurements and the g_{HZZ} measurements via the recoil mass methods leads to a direct, model independent determination of Higgs total width, therefore this measurement is of strong physics interests. The $Br(H \rightarrow WW^*)$ also a gateway measurement to the absolute Higgs width measurement. In addition, the large statistic of $H \rightarrow WW^*$ events makes it a sensitive probe to the new physics.

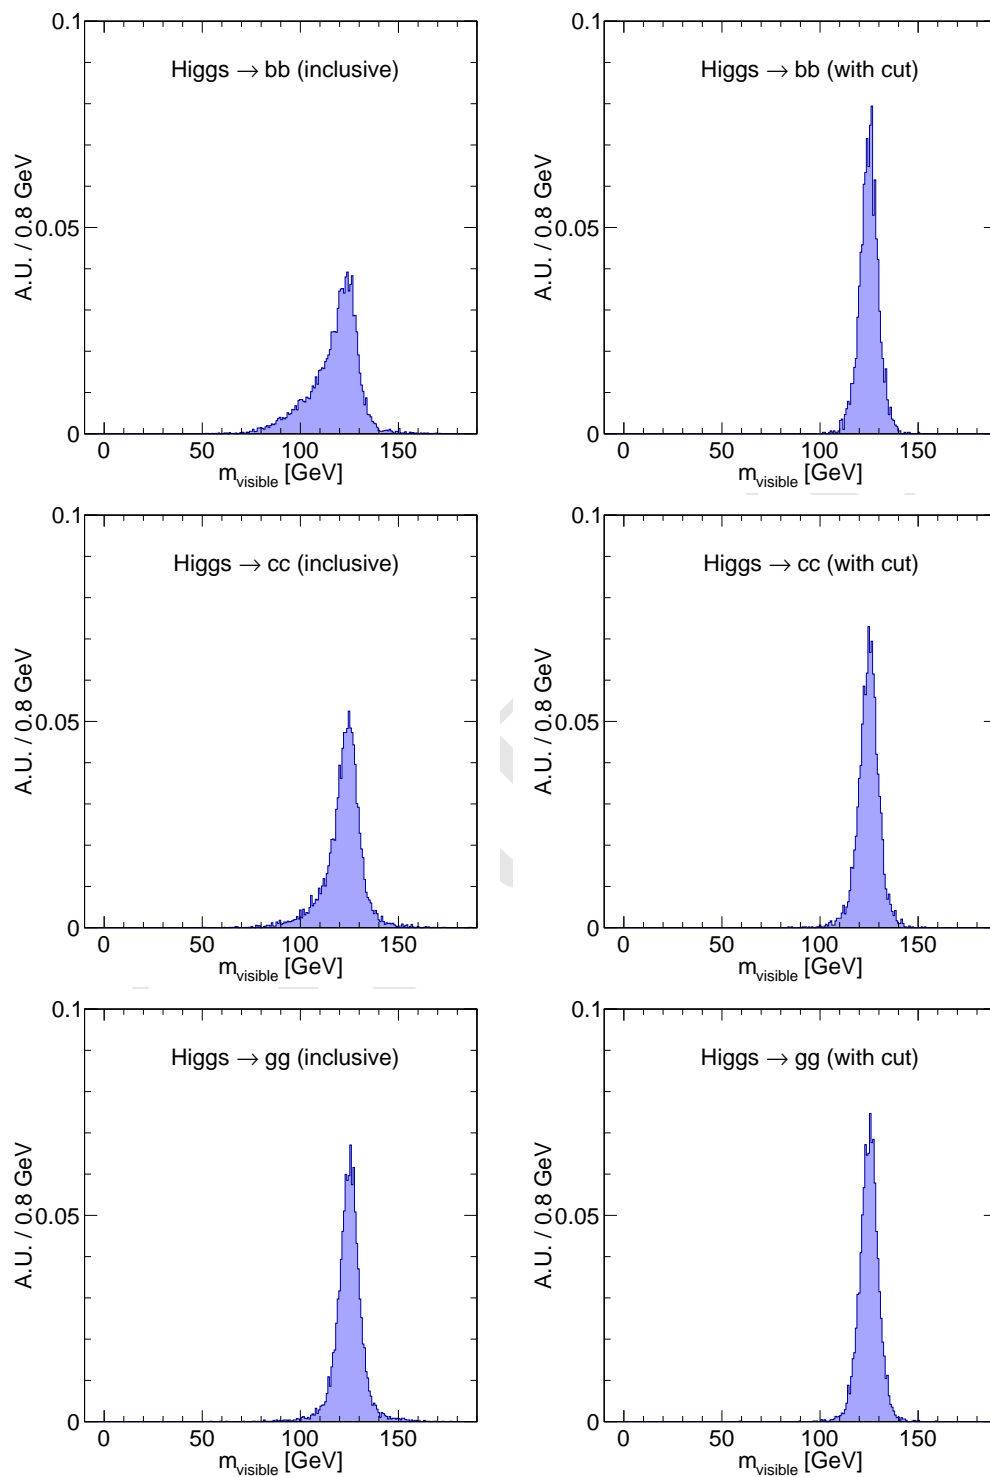

Figure 10.17: Total visible mass distribution of $vvH, H \rightarrow di - jet$ events, with/without cleaning

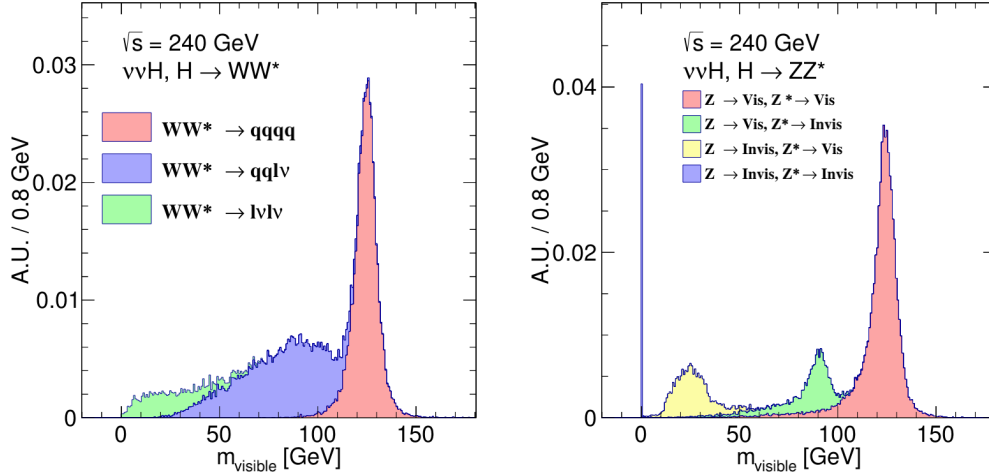

Figure 10.18: Total visible mass distribution of $H \rightarrow WW^*$ (Left) and $H \rightarrow ZZ^*$ events (right).

Both W and Z bosons decay into SM fermions except the top quarks. Therefore, a successful reconstruction of the $Br(H \rightarrow WW^*/ZZ^*)$ signal requires a proper reconstruction of leptons, taus, missing energy and jets.

The $H \rightarrow WW^*$ events could cascade decay into hadronic, semi-leptonic, and full-leptonic final states. The mass distributions corresponding to different decay modes are separated in the left hand plot of Fig. 10.18. A full mass peak, corresponding to the full-hadronic final states, could be clearly identified.

Four peaks could be identified at the distribution of $Br(H \rightarrow ZZ^*)$. The peak at zero corresponding to the total invisible decay mode where both Z and Z^* decays into neutrinos and has a branching ratio of roughly 4%. The peak at the Higgs boson mass (125 GeV) is corresponding to the total visible mode. The other two peaks are corresponding to the conjugation case where $Z \rightarrow \text{visible}, Z^* \rightarrow \text{invisible}$ and $Z^* \rightarrow \text{visible}, Z \rightarrow \text{visible}$. Because of the heavy flavor and τ component of the Z boson decay, the peak at 125 GeV and at the Z boson mass exhibit a tail at the low mass side. For both $H \rightarrow WW^*$ and $H \rightarrow ZZ^*$ final states, a relative mass resolution of 3.8% is achieved with the full visible peak, which is consistent with the results at $H \rightarrow 2\text{jets}$ final states.

Fig. ?? exhibits beautiful separations of different components of $H \rightarrow ZZ^*$ events, those clear signature is highly appreciated in the physics measurements.

10.3.8 Jet flavor tagging

Identification of the jet flavor is essentially for the measurement of the Higgs couplings ($g(Hb\bar{b}), g(Hc\bar{c}), g(Hgg)$) and the EW observables at the CEPC. During the jet fragmentation cascade, the heavy flavor quarks (b and c) are mostly fragmented into heavy hadrons (i.e. $B^0, B^\pm, B_s, D^0, D^\pm, \text{etc}$). Those heavy hadrons have a typical $c\tau$ of a few hundred micrometers. Therefore, the reconstruction of the secondary vertex is crucial for the flavor tagging. The information of jet mass, vertex mass, number of leptons, etc, are also frequently used in flavor tagging.

Technically, the flavor tagging is operated using the LCFIPlus package [?], the default flavor tagging algorithm for the linear collider studies. At CEPC studies, the LCFIPlus takes the reconstructed final state particles from Arbor, reconstructs the sec-

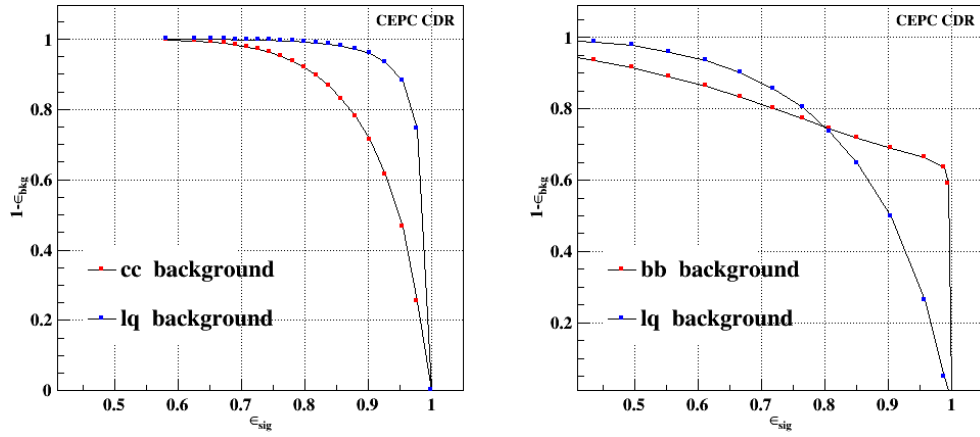

Figure 10.19: The jet flavor tagging performance using Arbor and LCFIPlus reconstruction at APODIS.

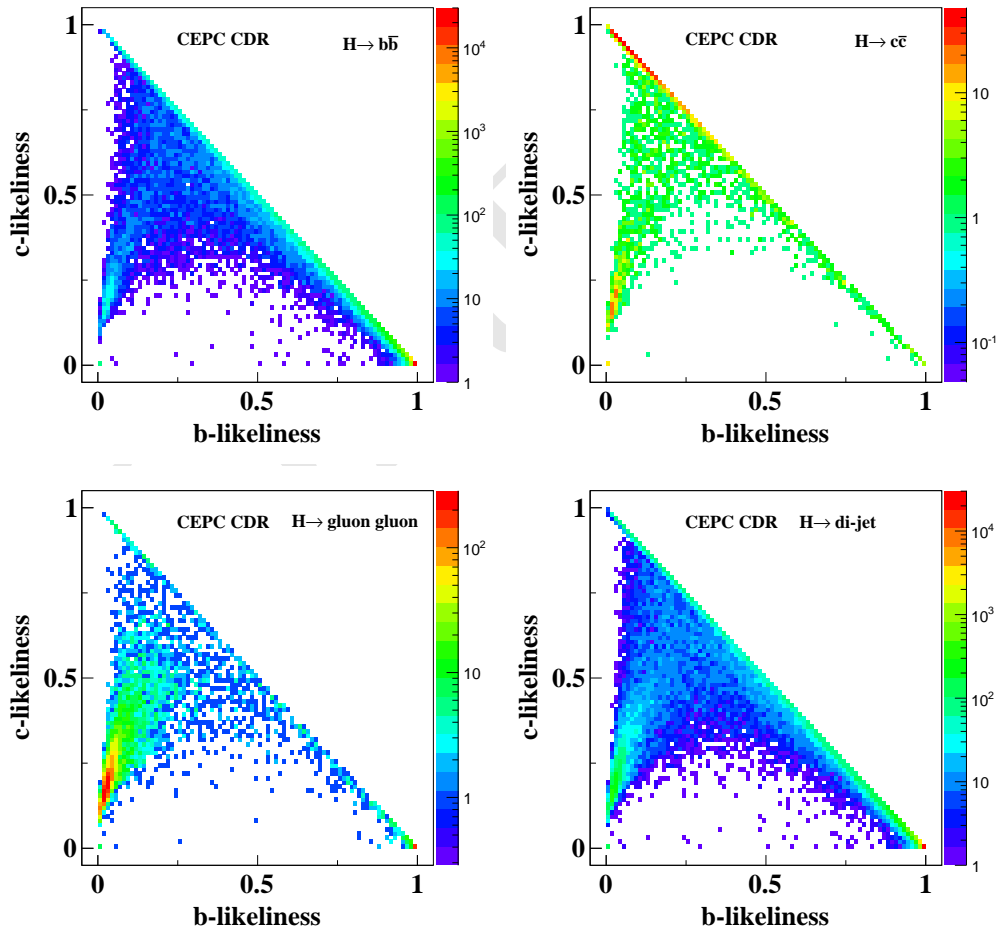

Figure 10.20: The heavy flavor jet likelihoods for Higgs samples: a, $H \rightarrow bb$; b $H \rightarrow cc$; c, $H \rightarrow gg$, and d, $H \rightarrow 2jets$

ond vertexes and performs the flavor tagging. For each jet, LCFIPlus extracts more than 60 distinguish observables and calculates the corresponding b -likeliness and c -likeliness using the Boost Decision Tree method [1]. Since the B -mesons have longer lifetime compared to the D -mesons, the c -tagging is much more challenging than the b -tagging. Thanks to the high precision vertex system, the c -jet could be distinguished from other jets at the ILD detector and the CEPC detector. Fig. 10.19 shows the reference ROC curve trained on $Z \rightarrow q\bar{q}$ sample at 91.2 GeV center of mass energy. The X -axis indicates the b/c -jet efficiency, while the Y -axis represents the surviving rate for the backgrounds.

Applying to the inclusive $Z \rightarrow q\bar{q}$ sample, the typical performance of the b -tagging reaches an efficiency/purity of 80%/90%, changing the working point to a reduced efficiency of 60%, the purity could be enhanced close to 100%. While for c -tagging, a typical working point has the efficiency/purity of 60%/60%.

The distribution on the phase space for $H \rightarrow 2\text{jets}$ samples are displayed in Fig. 10.20. Depending on the Higgs decay final states, those distributions clearly exhibits different patterns. It should be emphasized that, with the current detector geometry design and reconstruction algorithm, the c -tagging is still very difficult. As a result, the accuracy of $g(Hc\bar{c})$ measurement is largely limited by the contamination from the $H \rightarrow b\bar{b}$ events.

10.4 Conclusion

Targeting at precise measurements of the Higgs boson properties and the EW observables, the CEPC detector is required to reconstruct all the corresponding physics objects at high efficiency and high accuracy. The performance of the baseline detector design, the APODIS, has been intensively analyzed at full simulation level. The following object level performances have been achieved.

- 1, Lepton identification: $\epsilon_{e \rightarrow e} > 99.5\%$, $\epsilon_{\mu \rightarrow \mu} > 99.5\%$, $P_{h \rightarrow lepton} < 1\%$ for isolated tracks with energy larger than 2 GeV;
- 2, Charged Kaon identification: efficiency/purity of 95%/95% at inclusive Z pole sample with the energy range of 2 - 20 GeV;
- 3, Photon reconstruction: a relative accuracy of 1.7%/2.6% is achieved for the Higgs mass reconstruction at $H \rightarrow \gamma\gamma$ event using simplified/APODIS detector geometry;
- 5, Jet energy resolution: A relative accuracy of 3.8% of Boson mass reconstruction is achieved at a cleaned $H \rightarrow gg$ event sample. The Higgs boson, the Z boson, and the W boson can be efficiently separated from each other in their hadronic decay modes. The jet energy scale is controlled to 1% level. At individual jet, the relative jet energy varies from 3% to 6%, depending on the jet transverse momentum.
- 6, Jet Flavor Tagging: at the inclusive $Z \rightarrow q\bar{q}$ samples at 91.2 GeV, the b -jets could be identified with an efficiency/purity of 80%/90%; while the c -jets could be identified with efficiency/purity of 60%/60%.

Essentially, all the physics objects are successfully reconstructed by the CEPC baseline. The performances at the single particle level, such as the leptons, the kaons, and

	Higgs $\rightarrow \mu\mu$	Higgs $\rightarrow \gamma\gamma$	Higgs $\rightarrow b\bar{b}$
CEPC (APODIS)	0.20%	2.59%	3.63%
LHC (CMS, ATLAS)	$\sim 2\%$ [? ?]	$\sim 1.5\%$ [? ?]	$\sim 10\%$ [? ?]

Table 10.3: Higgs boson mass resolution ($\sigma/Mean$) at different decay modes with jets as final state particles, after the event cleaning

the photons at simplified geometry, are close to the physics and/or hardware limits. The separation and high-efficiency reconstruction of charged particles/photons ensure good τ lepton reconstruction. The jet energy resolution leads to a clear separation between massive bosons at di-jet events. The LCFIPlus algorithm could then distinguish b-jet, c-jet, and light-jet from each other.

A comprehensive analysis of the Higgs signal distributions shows that the SM Higgs signals are well established and have clean signatures. Based on the APODIS detector design, we characterize the Higgs signatures at the $e^+e^- \rightarrow \nu\nu Higgs$ events. The detector resolution could then be directly characterized by the mass resolution with Higgs $\rightarrow \mu\mu, \gamma\gamma$, and jet final states. Comparing to the LHC, the reconstruction accuracy at Higgs $\rightarrow \mu\mu$ events is improved by about one magnitude, and that at Higgs \rightarrow di-jets events is improved by about 3 times. The resolution at Higgs $\rightarrow \gamma\gamma$ events degrades by roughly 30-60%, limited by the absence of geometry based correction and fine-tuned calibration, and the sampling fraction of ECAL, see Table 10.3.

To conclude, the baseline design fulfills the physics requirements discussed in Chapter 3.

CHAPTER 11

BENCHMARK PHYSICS

The historic discovery of a Higgs boson in 2012 by the ATLAS and CMS collaborations [1, 2] and the subsequent studies of the properties of the particle [3–9] indicate the compatibility with the Standard Model (SM) predictions. Although all of the particles in the SM have been discovered, some fundamental questions, e.g. vast difference between the Planck scale and the weak scale, the nature of electroweak phase transition have not been fully understood. The attempt to further address those questions will involve the new physics beyond the SM which could lead a deviation from SM expectations for the precision measurement of the SM. A circular electron positron collider will provide an unique opportunity to have precise measurements of the Higgs, W and Z properties.

The CEPC produces huge statistics of massive SM Bosons. Its physics potential is explored on two different classes of physics benchmarks, the Higgs physics, the precision EW physics. Using the software tools introduced in section 10.2, the physics potential on Higgs physics is analyzed at full simulation level, see section ???. The accuracies on the EW precision measurements are mainly limited by systematic errors and are estimated in section 11.2. The synergies of these different physics measurements, the complimentary and comparison to the HL-LHC and other high energy physics programs are discussed in Chapter 12.

11.1 Higgs Boson Physics

JQ: Need to improve the summary and the flow, fill missing info and check numbers, reconcile with the white paper, notation consistency... otherwise it is in a reasonable good shape for proof reading... will resume editing from July 31 onwards...

At the CEPC, in contrast to the LHC, Higgs boson candidate events can be identified through a technique known as the recoil mass method without tagging its decays. Therefore, Higgs boson production can be disentangled from its decay in a model independent way. Moreover, the cleaner environment at a lepton collider allows much better exclusive measurement of Higgs boson decay channels. All of these give the CEPC impressive reach in probing Higgs boson properties. In this section, the results of the current CEPC simulation studies on the precision of the Higgs boson property measurements are summarized. In addition, reaches based on phenomenological studies in searching for exotic decays and in CP admixture of the Higgs boson are also included.

11.1.1 Higgs boson production and decay

Production processes for a 125 GeV SM Higgs boson at the CEPC are $e^+e^- \rightarrow ZH$ (ZH or Higgsstrahlung), $e^+e^- \rightarrow \nu\bar{\nu}H$ ($\nu\bar{\nu}H$ or W fusion) and $e^+e^- \rightarrow e^+e^-H$ (eeH or Z fusion) as illustrated in Fig. 11.1. The W and Z fusion processes are collectively referred to as vector-boson fusion (VBF) production.

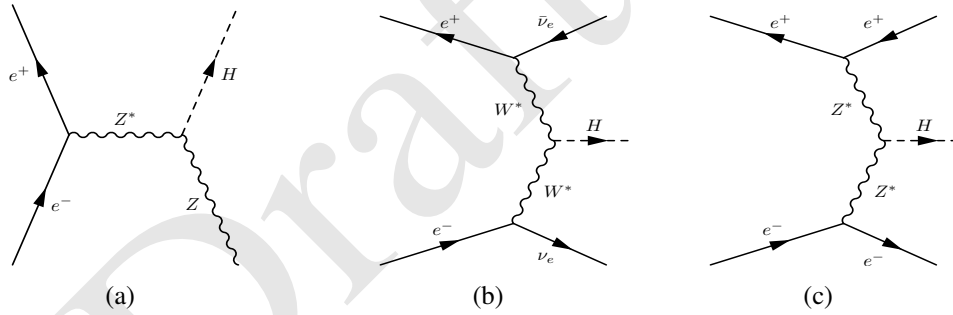

Figure 11.1: Feynman diagrams of the Higgs boson production processes at the CEPC: (a) $e^+e^- \rightarrow ZH$, (b) $e^+e^- \rightarrow \nu\bar{\nu}H$ and (c) $e^+e^- \rightarrow e^+e^-H$.

The total and individual cross sections for the production of a SM Higgs boson with a mass of 125 GeV as functions of center-of-mass energy are plotted in Fig. 11.2 while its decay branching ratios and total width are shown in Table 11.1. As an s -channel process, the cross section of the $e^+e^- \rightarrow ZH$ process reaches its maximum at $\sqrt{s} \sim 250$ GeV, and then decreases asymptotically as $1/s$. The VBF production processes are through t -channel exchanges of vector bosons. Their cross sections increase logarithmically as $\ln^2(s/M_V^2)$. Because of the accidental small neutral-current Zee coupling, the VBF cross section is dominated by the W fusion process. Numerical values of these cross sections at $\sqrt{s} = 240$ GeV are listed in Table 11.2.

The CEPC as a Higgs boson factory is designed to deliver a total of 5 ab^{-1} integrated luminosity to two detectors in 7 years. Over 10^6 Higgs boson events will be produced during this period. The large statistics, well-defined event kinematics and clean collision environment will enable the CEPC to measure Higgs boson production cross sections as

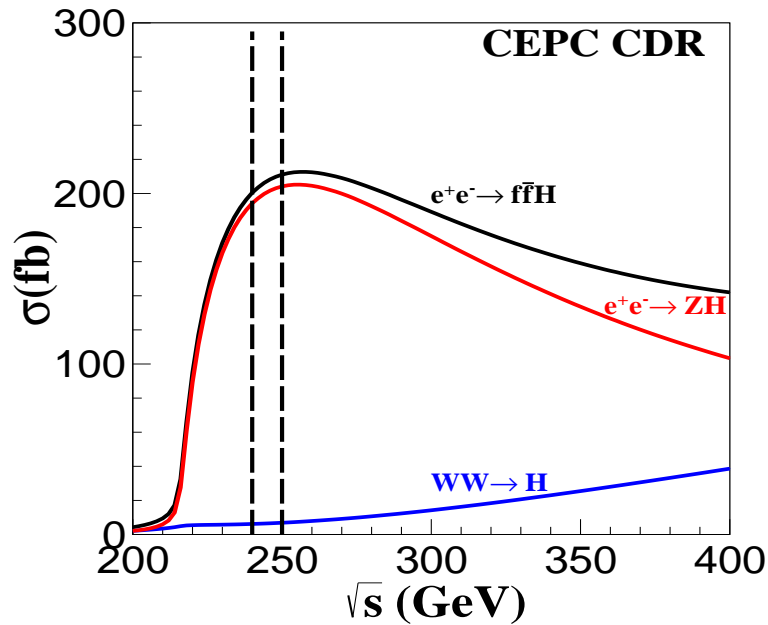

Figure 11.2: Production cross sections of $e^+e^- \rightarrow ZH$ and $e^+e^- \rightarrow (e^+e^-/\nu\bar{\nu})H$ as functions of \sqrt{s} for a 125 GeV SM Higgs boson. *Can still use some improvements...*

Table 11.1: Standard model predictions of the decay branching ratios and total width of a 125 GeV Higgs boson. These numbers are obtained from Refs. [1, 2].

Decay mode	Branching ratio	Relative uncertainties
$H \rightarrow b\bar{b}$	57.7%	+3.2%, -3.3%
$H \rightarrow c\bar{c}$	2.91%	+12%, -12%
$H \rightarrow \tau^+\tau^-$	6.32%	+5.7%, -5.7%
$H \rightarrow \mu^+\mu^-$	2.19×10^{-4}	+6.0%, -5.9%
$H \rightarrow WW^*$	21.5%	+4.3%, -4.2%
$H \rightarrow ZZ^*$	2.64%	+4.3%, -4.2%
$H \rightarrow \gamma\gamma$	2.28×10^{-3}	+5.0%, -4.9%
$H \rightarrow Z\gamma$	1.53×10^{-3}	+9.0%, -8.8%
$H \rightarrow \gamma\gamma$	8.57%	+10%, -10%
Γ_H	4.07 MeV	+4.0%, -4.0%

well as its properties (mass, decay width and branching ratios, etc.) with precision far beyond those achievable at the LHC. Compared with hadron collisions, e^+e^- collisions are unaffected by underlying event and pile-up effects. Theoretical calculations are less dependent on higher order QCD radiative corrections. Therefore, more precise tests of theoretical predictions can be performed at the CEPC. The tagging of $e^+e^- \rightarrow ZH$ events

Table 11.2: Cross sections of Higgs boson production and other SM processes at $\sqrt{s} = 250$ GeV and numbers of events expected in 5 ab^{-1} . The cross sections are calculated using the Whizard program [3]. Note that cross sections do not include potential interference effects between the same final states from different processes after W and Z boson decays (see text). **The numbers need to be updated to 240 GeV.**

Process	Cross section	Events in 5 ab^{-1}
Higgs boson production, cross section in fb		
$e^+e^- \rightarrow ZH$	204.7	1.02×10^6
$e^+e^- \rightarrow \nu\bar{\nu}H$	6.85	3.43×10^4
$e^+e^- \rightarrow e^+e^-H$	0.63	3.15×10^3
Total	212.1	1.06×10^6
Background processes, cross section in pb		
$e^+e^- \rightarrow e^+e^-$ (Bhabha)	25.1	1.3×10^8
$e^+e^- \rightarrow q\bar{q}(\gamma)$	50.2	2.5×10^8
$e^+e^- \rightarrow \mu^+\mu^-(\gamma)$ [or $\tau^+\tau^-(\gamma)$]	4.40	2.2×10^7
$e^+e^- \rightarrow WW$	15.4	7.7×10^7
$e^+e^- \rightarrow ZZ$	1.03	5.2×10^6
$e^+e^- \rightarrow e^+e^-Z$	4.73	2.4×10^7
$e^+e^- \rightarrow e^+\nu W^-/e^-\bar{\nu}W^+$	5.14	2.6×10^7

using the invariant mass of the system recoiling against the Z boson, independent of the Higgs boson decay, is unique to lepton colliders. It provides a powerful tool for the model-independent measurements of the inclusive $e^+e^- \rightarrow ZH$ production cross section, $\sigma(ZH)$, and of Higgs boson decay branching ratios. Combinations of these measurements will enable to determine the total Higgs boson decay width and to extract the Higgs boson couplings to fermions and vector bosons, providing sensitive probes to potential new physics beyond the SM.

SM background processes include $e^+e^- \rightarrow e^+e^-$ (Bhabha scattering), $e^+e^- \rightarrow Z\gamma$ (ISR return), $e^+e^- \rightarrow WW/ZZ$ (diboson) as well as the single boson production of $e^+e^- \rightarrow e^+e^-Z$ and $e^+e^- \rightarrow e^+\nu W^-/e^-\bar{\nu}W^+$. Their cross sections and expected numbers of events for an integrated luminosity of 5 ab^{-1} at $\sqrt{s} = 240$ GeV are shown in Table 11.2 as well. The energy dependence of the cross sections for these and the Higgs boson production processes are shown Fig. ?? . Note that many of these processes can lead to identical final states and thus can interfere. For example, $e^+e^- \rightarrow e^+\nu_e W^- \rightarrow e^+\nu_e e^-\bar{\nu}_e$ and $e^+e^- \rightarrow e^+e^-Z \rightarrow e^+e^-\nu_e\bar{\nu}_e$ have the same final state. Unless otherwise noted, these processes are simulated together to take into account interference effects for the studies presented in this paper.

11.1.2 Higgs boson tagging

Perhaps the most striking difference between hadron-hadron and e^+e^- collisions is that electron and positron are fundamental particles whereas hadrons are composite particles. Consequently the energy of e^+e^- collisions is known. Therefore through the energy and momentum conservation, the energy and momentum of a Higgs boson can be inferred from other particles in an event without examining the Higgs boson itself. For a Higgsstrahlung event where the Z boson decays to a pair of visible fermions (ff), the mass of the system recoiling against the Z boson, commonly known as the recoil mass, can be calculated assuming the event has a total energy \sqrt{s} and zero total momentum:

$$M_{\text{recoil}}^2 = (\sqrt{s} - E_{ff})^2 - p_{ff}^2 = s - 2E_{ff}\sqrt{s} + m_{ff}^2. \quad (11.1)$$

Here E_{ff} , p_{ff} and m_{ff} are, respectively, the total energy, momentum and invariant mass of the fermion pair. The M_{recoil} distribution should show a peak at the Higgs boson mass m_H for $e^+e^- \rightarrow ZH$ and $e^+e^- \rightarrow e^+e^-H$ processes, and is expected to be smooth without a resonance structure for background processes in the mass region around 125 GeV. Two important measurements of the Higgs boson can be performed from the M_{recoil} mass spectrum. The Higgs boson mass can be determined from the position of the resonance in the spectrum. The width of the resonance structure is dominated by the beam energy spread (including ISR effects) and energy/momentum resolution of the detector as the natural Higgs boson width is only 4.07 MeV. The best precision of the mass measurement can be achieved from the leptonic $Z \rightarrow \ell\ell$ ($\ell = e, \mu$) decays. The height of the resonance is a measure of the Higgs boson production cross section $\sigma(ZH)$ ¹. Through the fitting to the M_{recoil} spectrum, the $e^+e^- \rightarrow ZH$ event yield, and therefore $\sigma(ZH)$, can be extracted, independent of Higgs boson decays. Higgs boson decay branching ratios can then be determined by measuring the ZH cross sections for individual Higgs boson decay modes. The recoil mass spectrum has been investigated for both leptonic and hadronic Z boson decays as presented below.

The leptonic Z decay is ideal for studying the recoil mass spectrum of the $e^+e^- \rightarrow ZX$ events. The decay is easily identifiable and the lepton momenta can be precisely measured. Figure 11.3 shows the reconstructed recoil mass spectra of $e^+e^- \rightarrow ZX$ candidates for the $Z \rightarrow \mu\mu$ and $Z \rightarrow ee$ decay modes. The analyses are based on the full detector simulation for the signal events and on the fast detector simulation for background events. They are performed with event selections entirely based on the information of the two leptons, independent of the final states of Higgs boson decays. This approach is essential for the measurement of the inclusive $e^+e^- \rightarrow ZH$ production cross section and the model-independent determination of the Higgs boson branching ratios. SM processes with at least 2 leptons in their final states are considered as backgrounds. As shown in Fig. 11.3, the analysis has a good signal-to-background ratio. The long high-mass tail is largely due to the initial-state radiation. Leading background contributions after the selection are from ZZ , WW and $Z\gamma$ events. Compared to the analysis of the $Z \rightarrow \mu\mu$ decay, the analysis of the $Z \rightarrow ee$ decay suffers from additional and large background contributions from Bhabha and single boson production.

The recoil mass technique can also be applied to the hadronic Z boson decays ($Z \rightarrow q\bar{q}$) of the $e^+e^- \rightarrow ZX$ candidates. This analysis benefits from a larger $Z \rightarrow q\bar{q}$ decay

¹For the $Z \rightarrow ee$ decay, there will be a small contribution from $e^+e^- \rightarrow e^+e^-H$ production.

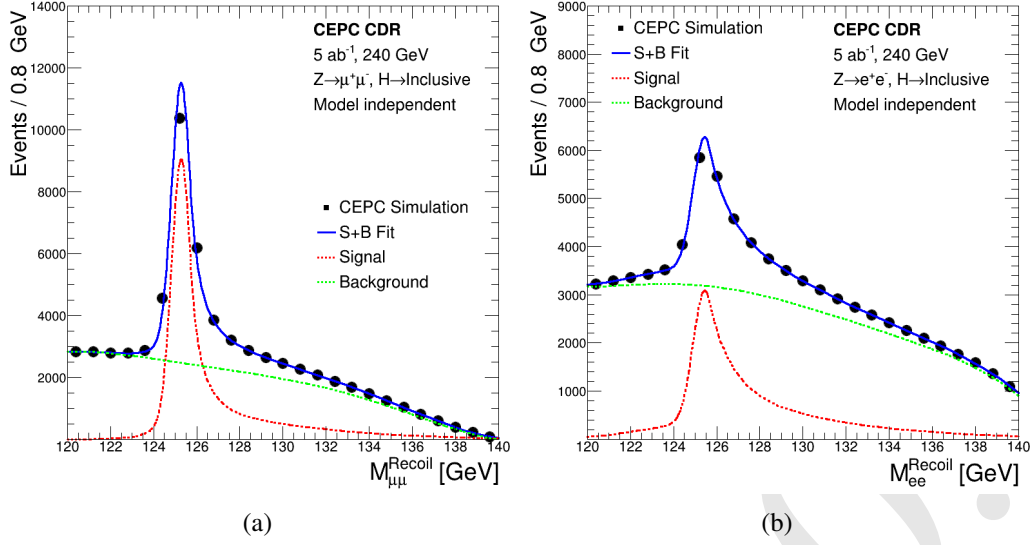

Figure 11.3: The recoil mass spectra of $e^+e^- \rightarrow ZX$ candidates for (a) $Z \rightarrow \mu\mu$ and (b) $Z \rightarrow ee$ with an integrated luminosity of 5 ab^{-1} .

branching ratio, but suffers from worse jet energy resolution compared with the track momentum and electromagnetic energy resolutions. In addition, ambiguity in selecting jets from the $Z \rightarrow q\bar{q}$ decay, particularly in events with hadronic decays of the Higgs boson, can degrade the analysis performance and also introduce model dependences. Therefore, the measurement is highly dependent on the performance of the PFA and the jet clustering algorithm. Following the same approach as the ILC study [4], an analysis based on the fast simulation has been performed. After the event selection, main backgrounds arise from $Z\gamma$'s and WW production.

11.1.3 Measurements of $\sigma(ZH)$ and m_H

The inclusive $e^+e^- \rightarrow ZH$ production cross section $\sigma(ZH)$ and Higgs boson mass m_H can be extracted from fits to the recoil mass distributions of the $e^+e^- \rightarrow ZX \rightarrow (\ell^+\ell^-/q\bar{q})X$ candidates. For the leptonic $Z \rightarrow \ell\ell$ decays, the recoil mass distribution of the signal process $e^+e^- \rightarrow ZH$ (and also $e^+e^- \rightarrow e^+e^-H$ in case of the $Z \rightarrow ee$ decay) is modeled with a Crystal Ball function [5] whereas the total background is modeled with a polynomial function in the fit. As noted above, the recoil mass distribution is insensitive to the intrinsic Higgs boson width if it were as small as predicted by the SM. The Higgs boson mass can be determined with precision of 6.5 MeV and 14 MeV from the $Z \rightarrow \mu\mu$ and $Z \rightarrow ee$ decay modes, respectively. In combination, an uncertainty of 5.9 MeV can be achieved. $e^+e^- \rightarrow ZX \rightarrow q\bar{q}X$ events contribute little to the precision of the m_H measurement due to the poor $Z \rightarrow q\bar{q}$ mass resolution, but dominates the precision of the $e^+e^- \rightarrow ZH$ cross section measurement benefiting from its large statistics. A relative precision of 0.65% of $\sigma(ZH)$ is predicted from a simple event counting analysis. In comparison, the corresponding precision from the $Z \rightarrow ee$ and $Z \rightarrow \mu\mu$ decays is estimated to be 2.1% and 0.9%, respectively. The combined precision of the three measurements is 0.5%.

For the model-independent measurement of $\sigma(ZH)$, event selections independent of the Higgs boson decays are essential. However, additional selections using the Higgs boson decay information can be applied to improve the Higgs boson mass measurement. This will be particularly effective in suppressing the large backgrounds in the $Z \rightarrow ee$ and $Z \rightarrow q\bar{q}$ decay modes. This improvement is not implemented in the current study.

11.1.4 Analyses of individual Higgs boson decay modes

A bit too wordy, repetitive? Too many plots?

Different decay modes of the Higgs boson can be identified through their unique signatures, enabling the measurements of production rates for these decays. For the Higgs boson production through the $e^+e^- \rightarrow ZH$ process in particular, candidate events can be tagged from the visible decays of the Z bosons, Higgs boson decays can then be probed by studying the rest of the events. Simulation studies of the CEPC conceptual detector have been performed for the Higgs boson decay modes of $H \rightarrow b\bar{b}/c\bar{c}/gg$, $H \rightarrow WW^*$, $H \rightarrow ZZ^*$, $H \rightarrow \gamma\gamma$, $H \rightarrow Z\gamma$, $H \rightarrow \tau^+\tau^-$, $H \rightarrow \mu^+\mu^-$ and $H \rightarrow \text{inv}$. The large numbers of the decay modes of H , W and Z boson as well as the τ -lepton lead to a very rich variety of event topologies. This complexity makes it impractical to investigate the full list of final states descending from the Higgs boson decays. Instead, a limited number of final states of individual Higgs boson decay mode is considered. The dominant backgrounds come from SM diboson production and Z production with initial or final state radiations.

The studies are optimized for the dominant ZH process, however the $e^+e^- \rightarrow \nu\bar{\nu}H$ and $e^+e^- \rightarrow e^+e^-H$ processes are included whenever applicable. The production cross sections of individual decay mode, $\sigma(ZH) \times \text{BR}$, are extracted. Combined with the inclusive $\sigma(ZH)$ measurement, these measurements will permit the determinations of the Higgs boson decay branching ratios in a model-independent way. Below main features of these studies are described and their results are presented in Section 11.1.5.

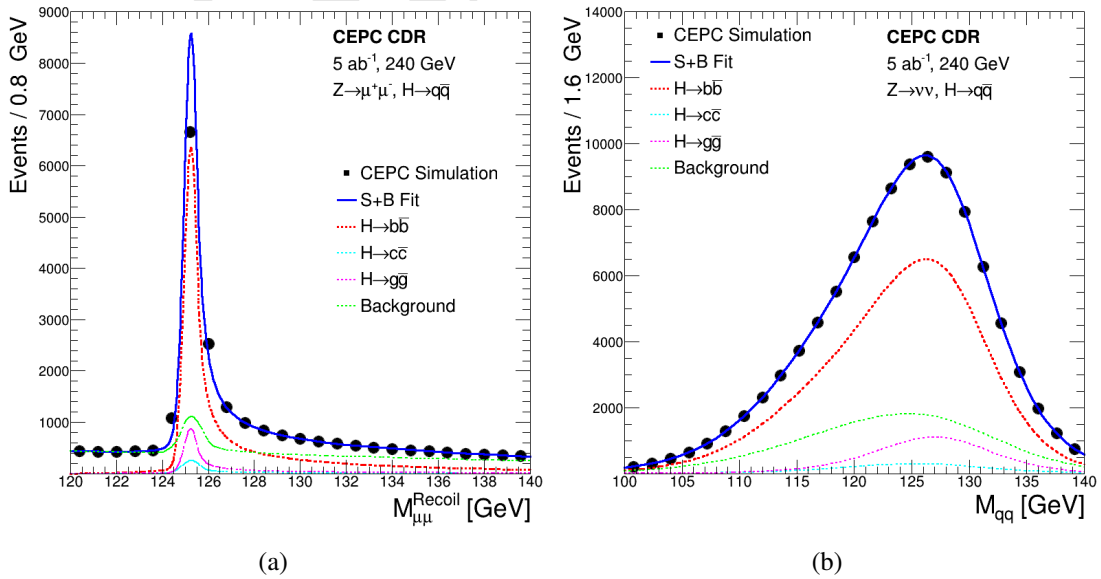

Figure 11.4: (a) ZH production with $H \rightarrow b\bar{b}/c\bar{c}/gg$ decays: distributions of (a) the recoil mass of $Z \rightarrow \mu\mu$ and (b) the dijet invariant mass distribution the $Z \rightarrow \nu\bar{\nu}$ analysis.

For a SM Higgs boson with a mass of 125 GeV, nearly 70% of all Higgs bosons decay into a pair of jets: b -quarks (57.7%), c -quarks (2.9%) and gluons (8.6%). While the $H \rightarrow b\bar{b}$ decay has been observed at the LHC, the $H \rightarrow c\bar{c}$ and $H \rightarrow g\bar{g}$ decays are difficult, if not impossible, to be conclusively identified even at the HL-LHC due to large backgrounds. In comparison, these three decays can be isolated and studied at the CEPC in detail. This is important as the $H \rightarrow c\bar{c}$ decay is likely the only vehicle for investigating Higgs boson coupling to the second-generation quarks. The study considers all Z boson decay modes except $Z \rightarrow \tau^+\tau^-$. The $H \rightarrow b\bar{b}/c\bar{c}/g\bar{g}$ candidates are identified through the dijet invariant mass, or the recoil mass of the visible Z boson decays, or both. Jet flavor tagging is employed to statistically separate $H \rightarrow b\bar{b}, c\bar{c}, g\bar{g}$ contributions. Figure 11.5(a) shows the recoil mass distribution of the $Z \rightarrow \mu\mu$ analysis. Compared with the distribution of the analysis of inclusive Higgs boson decays shown in Fig. 11.3(a), the background is significantly reduced through the selection of specific Higgs boson decays. Figure 11.5(b) is the dijet mass distribution of the $Z \rightarrow \nu\bar{\nu}$ analysis, showing excellent signal-to-background ratio and good dijet mass resolution.

The W -fusion process of $e^+e^- \rightarrow \nu\bar{\nu}H$ has a cross section of **XX%** of that of the ZH process at $\sqrt{s} = 240$ GeV in the SM. This process has been explored for the $H \rightarrow b\bar{b}$ decay mode. The analysis suffers from large backgrounds from $ZH \rightarrow \nu\bar{\nu}b\bar{b}$ as it has the same final state. However, the $\nu\bar{\nu}H$ and $Z(\nu\bar{\nu})H$ contributions can be separated through the exploration of their kinematic differences. Higgs bosons are produced with different polar angular distributions. Moreover, the recoil mass distribution should exhibit a resonance structure at the Z boson mass for $Z(\nu\bar{\nu})H$ and show a continuum spectrum for $e^+e^- \rightarrow \nu\bar{\nu}H$. The $\nu\bar{\nu}H$ contribution is extracted through a fit to the two-dimensional distribution of the cosine of the polar angle and the recoil mass.

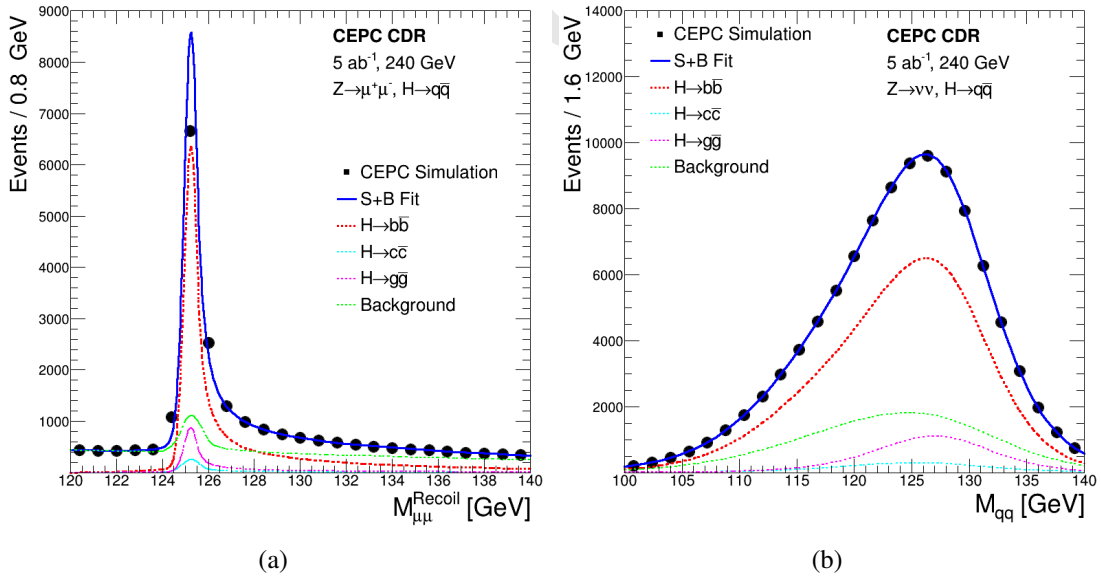

Figure 11.5: (a) ZH production with $H \rightarrow b\bar{b}/c\bar{c}/g\bar{g}$ decays: distributions of (a) the recoil mass of $Z \rightarrow \mu\mu$ and (b) the dijet invariant mass distribution the $Z \rightarrow \nu\bar{\nu}$ analysis.

The $H \rightarrow WW^*$ and $H \rightarrow ZZ^*$ decays are among the first decay modes studied at the LHC and are critical for the discovery of the Higgs boson thanks to the clean leptonic signatures of the W or Z boson decays. However due to their large backgrounds, hadronic

final states of the $H \rightarrow WW^*$ and $H \rightarrow ZZ^*$ decays are out of reach at the LHC despite of their larger branching ratios than leptonic final states. This is not the case at the CEPC. In fact, most of the sensitivities to these two Higgs boson decay modes at the CEPC are expected to be from final states with one or both vector bosons decay hadronically. A number of selected final states have been studied. For $H \rightarrow WW^*$, the final states included are $Z \rightarrow \ell\ell$, $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu, \ell\nu q\bar{q}$; $Z \rightarrow \nu\bar{\nu}$, $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu, q\bar{q}q\bar{q}$ and $Z \rightarrow q\bar{q}$, $H \rightarrow WW^* \rightarrow q\bar{q}q\bar{q}$. For $H \rightarrow ZZ^*$, they are $Z \rightarrow \mu\mu$, $H \rightarrow ZZ^* \rightarrow \nu\bar{\nu}q\bar{q}$ and $Z \rightarrow \nu\bar{\nu}$, $H \rightarrow ZZ^* \rightarrow \ell\ell q\bar{q}$. A combination of the recoil mass, the invariant mass of the $W \rightarrow q\bar{q}$ and $Z \rightarrow q\bar{q}$ decay as well as the leptonic decay signatures of W and Z bosons are used to identify ZH events. Some of these analyses suffer from large backgrounds as shown, for example, in Fig. 11.6(a), while others are almost background free as illustrated in Fig. 11.6(b).

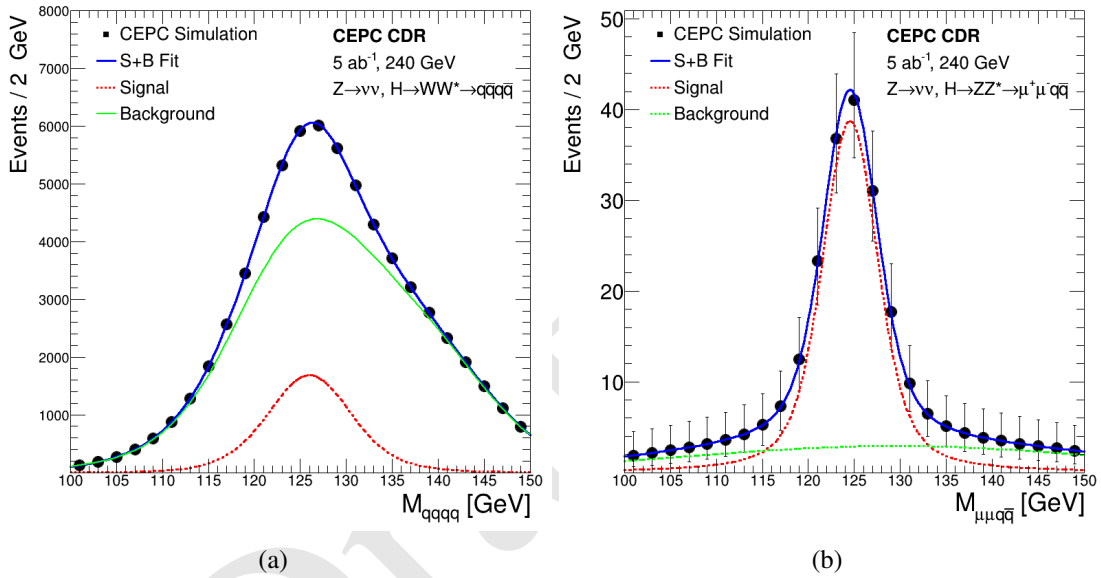

Figure 11.6: (a) ZH production with $H \rightarrow WW^* \rightarrow q\bar{q}q\bar{q}$ and $Z \rightarrow \nu\bar{\nu}$: the invariant mass of the 4-jet system. (b) ZH production with $H \rightarrow ZZ^* \rightarrow \mu^+\mu^- q\bar{q}$ and $Z \rightarrow \nu\bar{\nu}$: the invariant mass distribution of the dimuon and dijet system.

The $H \rightarrow \gamma\gamma$ and $H \rightarrow Z\gamma$ decays have small branching ratios in the SM as they proceed through W boson and top quark triangular loops. CEPC's sensitivities to these two decay modes have been examined. The $H \rightarrow \gamma\gamma$ analysis of ZH production suffers from large $e^+e^- \rightarrow (Z/\gamma^*)\gamma\gamma$ background where γ 's arise from the initial and final state radiations. All Z boson decay modes other than the $Z \rightarrow ee$ decay are considered for the $H \rightarrow \gamma\gamma$ studies. The $ZH \rightarrow e^+e^-\gamma\gamma$ decay has additional large backgrounds from Bhabha processes. As shown in Fig. 11.7(a), the $H \rightarrow \gamma\gamma$ signal is expected to appear as a resonance over a smooth background in the diphoton mass distribution. ZH production with $H \rightarrow Z\gamma$ decay will lead to events with two on-shell Z bosons and one photon. The $H \rightarrow Z\gamma$ study targeted the signal process of $ZH \rightarrow ZZ\gamma \rightarrow \nu\bar{\nu}q\bar{q}\gamma$. In this final state, the energy and momentum of the $\nu\bar{\nu}$ system can be calculated from the visible energy and momentum of the event. The mass difference between the Higgs boson candidate and the candidate of the associated Z boson can then be calculated. For signal events, this mass difference is expected to be $m_H - m_Z \sim 35$ GeV for correct combinations as

shown in Fig. 11.8(b). For background events and wrong combinations of signal events, the distribution should be smooth.

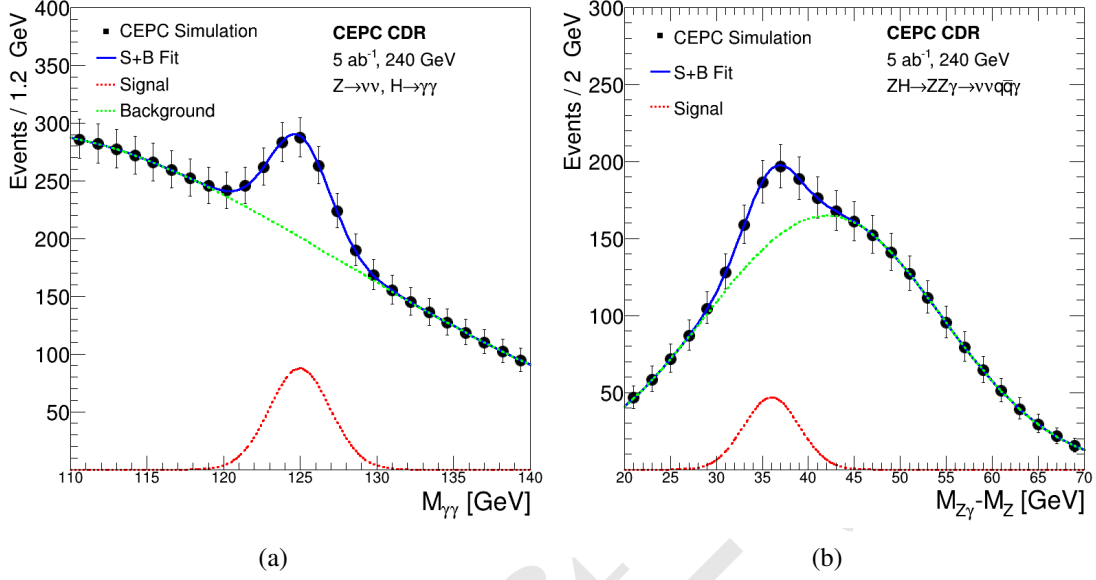

Figure 11.7: (a) ZH production with $H \rightarrow \gamma\gamma$: the invariant mass distribution of the selected photon pairs for $Z \rightarrow \nu\bar{\nu}$. (b) ZH production with $H \rightarrow Z\gamma$: the distribution of the mass difference between the reconstructed $Z\gamma$ and Z system.

Leptonic Higgs boson decays are accessible for $H \rightarrow \tau^+\tau^-$ and $H \rightarrow \mu^+\mu^-$ at the CEPC. Simulation studies of ZH production with the $H \rightarrow \tau^+\tau^-$ decay have been performed for all Z boson decay modes except $Z \rightarrow ee$. A boosted decision tree utilizing particle multiplicity and their separations is used to select di-tau candidates from $H \rightarrow \tau^+\tau^-$. An impact-parameter based variable of the leading track of the di-tau candidate is used as the final discriminant for the signal extraction. An example distribution of this variable for $Z \rightarrow \nu\bar{\nu}$ is shown Fig. 11.8(a). Similar to $H \rightarrow \gamma\gamma$, the $H \rightarrow \mu^+\mu^-$ decay also allows the reconstruction of the Higgs boson with high resolution. The signal is expected to appear as a resonance structure at m_H over the smooth background in the dimuon mass spectrum. Good dimuon mass resolution is essential for the performance. For this study, all Z boson decay modes are considered. Figure 11.8 shows the dimuon mass distribution combining all Z boson decay modes.

In the SM, the Higgs boson can decay invisibly via $H \rightarrow ZZ^* \rightarrow \nu\bar{\nu}\nu\bar{\nu}$ with a branching ratio of 1.06×10^{-3} . In many extensions to the SM, the Higgs boson can decay directly to invisible particles with significantly higher branching ratio. At the CEPC, the $H \rightarrow \text{inv}$ decay be directly identified the recoil mass of Z boson decays. The sensitivity is estimated for $Z \rightarrow \ell\bar{\ell}$ and $Z \rightarrow q\bar{q}$ decays. The SM $H \rightarrow ZZ^* \rightarrow \nu\bar{\nu}\nu\bar{\nu}$ decay is used to model the $H \rightarrow \text{inv}$ decay in both the SM and its extension. This is made possible by the fact that the Higgs boson is narrow scalar in the SM so that the production and decay are factorized.

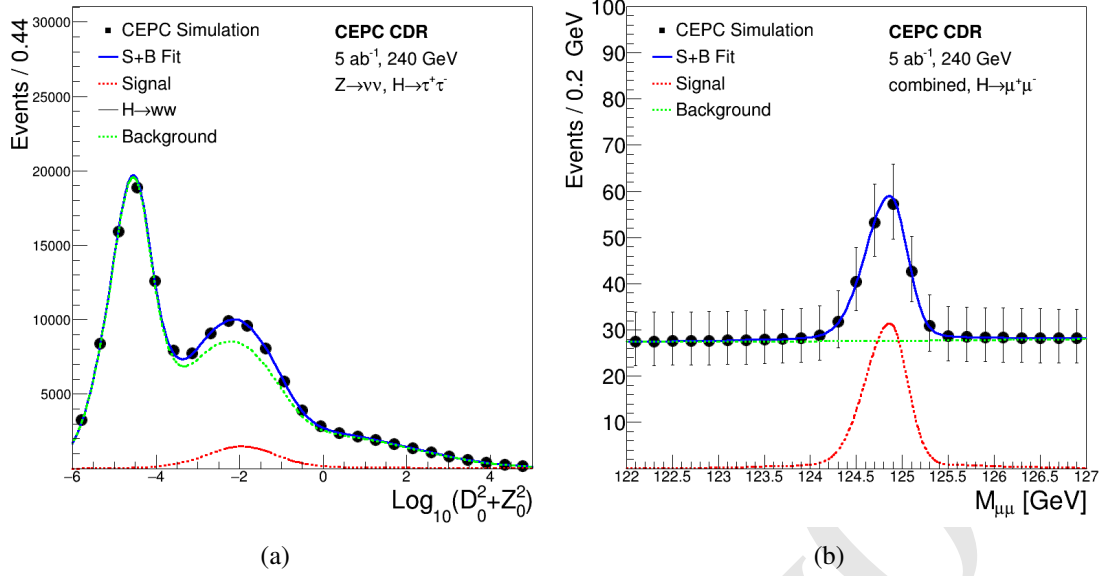

Figure 11.8: (a) ZH production with $H \rightarrow \tau^+\tau^-$: the distribution of impact parameter variable of the leading track of the di-tau candidates for the $Z \rightarrow \nu\bar{\nu}$ decay mode. (b) ZH production with $H \rightarrow \mu^+\mu^-$: the invariant mass distribution of the selected muon pairs combining all Z boson decay modes.

11.1.5 Combination of individual analyses

With the measurements of inclusive cross section $\sigma(ZH)$ and the cross sections of individual Higgs boson decay mode $\sigma(ZH) \times \text{BR}$, the Higgs boson decay branching ratio, BR, can be extracted. Most of the systematic uncertainties associated with the measurement of $\sigma(ZH)$ cancels in this procedure. A maximum likelihood fit is used to estimate the precision on BRs. For a given Higgs boson decay mode, the likelihood has the form:

$$L(\text{BR}, \theta) = \text{Poisson} [N^{\text{obs}} | N^{\text{exp}}(\text{BR}, \theta)] \cdot G(\theta), \quad (11.2)$$

where BR is the parameter of interest and θ represent nuisance parameters associated with systematic uncertainties. N^{obs} is the number of the observed events, $N^{\text{exp}}(\text{BR}, \theta)$ is the expected number of events, and $G(\theta)$ is a set of constraints on the nuisance parameters within their estimated uncertainties. The number of expected events is the sum of signal and background events. The number of signal events is calculated from the integrated luminosity, the $e^+e^- \rightarrow ZH$ cross section $\sigma(ZH)$ measured from the recoil method, Higgs boson branching ratio BR, the event selection efficiency ϵ . The number of the expected background events, N^b , is estimated from Monte Carlo samples. Thus

$$N^{\text{exp}}(\text{BR}, \theta) = \text{Lumi}(\theta^{\text{lumi}}) \times \sigma_{ZH}(\theta^\sigma) \times \text{BR} \times \epsilon(\theta^\epsilon) + N^b(\theta^b), \quad (11.3)$$

where θ^X ($X = \text{lumi}, \sigma, \epsilon$ and b) are the nuisance parameters of their corresponding parameters or measurements. Even with 10^6 Higgs boson events, statistical uncertainties are expected to be dominant and thus systematic uncertainties are not taken into account for the current studies. Thus the nuisance parameters are fixed to their nominal values.

Table 11.3: Estimated precision of Higgs boson property measurements expected from a CEPC dataset of 5 ab^{-1} at $\sqrt{s} = 240 \text{ GeV}$. All precision are relative except for m_H and $\text{BR}(H \rightarrow \text{inv})$ for which Δm_H and 95% CL upper limit on the BSM physics contribution are quoted respectively. **Missing BR precision**

Property	Estimated Precision
m_H	5.9 MeV
Γ_H	3.3%
$\sigma(ZH)$	0.50%
$\sigma(\nu\bar{\nu}H)$	3.05%

Decay mode	$\sigma(ZH) \times \text{BR}$	BR
$H \rightarrow b\bar{b}$	0.29%	%
$H \rightarrow c\bar{c}$	3.45%	%
$H \rightarrow gg$	1.37%	%
$H \rightarrow WW^*$	1.04%	%
$H \rightarrow ZZ^*$	5.21%	%
$H \rightarrow \gamma\gamma$	7.38%	%
$H \rightarrow Z\gamma$	21%	%
$H \rightarrow \tau^+\tau^-$	0.87%	%
$H \rightarrow \mu^+\mu^-$	16.8%	%
$H \rightarrow \text{inv}$	—	< 0.33%

Table 11.3 summarizes the estimated precision of Higgs boson property measurements, combining all studies described above and taking into account cross-feeds between different Higgs boson production processes and decay modes. For the leading Higgs boson decay modes, namely $b\bar{b}$, $c\bar{c}$, gg , WW^* , ZZ^* and $\tau^+\tau^-$, percent level precision are expected. The best achievable statistical uncertainties for 5 ab^{-1} are 0.28% for $\sigma(e^+e^- \rightarrow ZH) \times \text{BR}(H \rightarrow b\bar{b})$ and 0.5% for $\sigma(e^+e^- \rightarrow ZH)$. Even for these measurements, statistics is likely the dominant source of uncertainties. Systematic uncertainties from the efficiency/acceptance of the detector, the luminosity and the beam energy determination are expected to be small. The integrated luminosity can be measured with a 0.1% precision, a benchmark already achieved at the LEP [6], and can be potentially improved in the future. The center-of-mass energy will be known better than 1 MeV, resulting negligible uncertainties on the theoretical cross section predictions and experimental recoil mass measurements.

11.1.6 Higgs boson width

The Higgs boson width (Γ_H) is of special interest as it is sensitive to BSM physics in Higgs boson decays that are not directly detectable or searched for. However, the 4.07 MeV width predicted by the SM is too small to be measured with a reasonable precision from

the distributions of either the invariant mass of the Higgs boson decay products or the recoil mass of the system produced in association with the Higgs boson. Unique to lepton colliders, the width can be determined from the measurements of Higgs boson production cross sections and its decay branching ratios. This is because the inclusive $e^+e^- \rightarrow ZH$ cross section $\sigma(ZH)$ can be measured from the recoil mass distribution, independent of Higgs boson decays.

Measurements of $\sigma(ZH)$ and BR's have been discussed in Sections 11.1.2 and 11.1.4. Combining these measurements, the Higgs boson width can be calculated in a model-independent way:

$$\Gamma_H = \frac{\Gamma(H \rightarrow ZZ^*)}{\text{BR}(H \rightarrow ZZ^*)} \propto \frac{\sigma(ZH)}{\text{BR}(H \rightarrow ZZ^*)} \quad (11.4)$$

Here $\Gamma(H \rightarrow ZZ^*)$ is the partial width of the $H \rightarrow ZZ^*$ decay. Because of the small expected $\text{BR}(H \rightarrow ZZ^*)$ value for a 125 GeV Higgs boson (2.64% in the SM), the precision of Γ_H is limited by the $H \rightarrow ZZ^*$ statistics. It can be improved using the decay final states with the expected large BR values, for example the $H \rightarrow b\bar{b}$ decay:

$$\Gamma_H = \frac{\Gamma(H \rightarrow b\bar{b})}{\text{BR}(H \rightarrow b\bar{b})} \quad (11.5)$$

$\Gamma(H \rightarrow b\bar{b})$ can be independently extracted from the cross section of the W fusion process $e^+e^- \rightarrow \nu\bar{\nu}H \rightarrow \nu\bar{\nu}b\bar{b}$:

$$\sigma(\nu\bar{\nu}H \rightarrow \nu\bar{\nu}b\bar{b}) \propto \Gamma(H \rightarrow WW^*) \cdot \text{BR}(H \rightarrow b\bar{b}) = \Gamma(H \rightarrow b\bar{b}) \cdot \text{BR}(H \rightarrow WW^*) \quad (11.6)$$

Thus the Higgs boson total width

$$\Gamma_H = \frac{\Gamma(H \rightarrow b\bar{b})}{\text{BR}(H \rightarrow b\bar{b})} \propto \frac{\sigma(e^+e^- \rightarrow \nu\bar{\nu}H)}{\text{BR}(H \rightarrow WW^*)} \quad (11.7)$$

Here $\text{BR}(H \rightarrow b\bar{b})$ and $\text{BR}(H \rightarrow WW^*)$ are measured from the $e^+e^- \rightarrow ZH$ process. The limitation of this method is the precision of the $\sigma(e^+e^- \rightarrow \nu\bar{\nu}H)$ measurement.

The expected precision on Γ_H is 5.1% from the measurements of $\sigma(ZH)$ and $\text{BR}(H \rightarrow ZZ^*)$ and is 3.4% from the measurements of $\sigma(\nu\bar{\nu}H \rightarrow \nu\bar{\nu}b\bar{b})$, $\text{BR}(H \rightarrow b\bar{b})$ and $\text{BR}(H \rightarrow WW^*)$. The former is dominated by the precision of the $\text{BR}(H \rightarrow ZZ^*)$ measurement while the latter by the $\sigma(e^+e^- \rightarrow \nu\bar{\nu}H)$ measurement. The combined Γ_H precision of the two measurements is 3.2%, taking into account correlations between the two measurements.

11.1.7 Higgs Boson Coupling Measurements

To understand the implications of the predicted measurement precision shown in Table ?? on possible new physics models, one would need to translate them into constraints on the parameters in the Lagrangian. This is frequently referred to as Higgs boson coupling measurement, even though this way of phrasing it can be misleading as discussed in the following.

There are different ways of presenting the constraints. Before going into CEPC results, we briefly comment on the reasons behind choices of schemes in this section. First, the goal of theory interpretation is different from analyzing actual data, where a lot of detailed work will be done to derive the extended sets of observables. Instead, obtaining

a broad brushed big picture of the basic capability of the Higgs boson coupling measurement at the CEPC is the goal. Ideally, the presentation would be simple with a intuitive connection with the observables. The presentation would ideally also be free of underlying model assumptions. In addition, it would be convenient if the result presentation can be interfaced directly with higher order computations, RGE evolutions, and so on. However, achieving all of these goals simultaneously is not possible. Two of the most popular and balanced approaches are the so-called κ -framework and the Effective Field Theory (EFT) analysis. As discussed in more detail later, none of these is perfect. At the same time, neither of these is wrong as long as one is careful not to over interpreting the result. Another important aspect of making projections on the physics potential of a future experiment is that they will be compared with other possible future experiments. Hence, CEPC follows the most commonly used approaches to facilitate such comparisons.

Motivated by these arguments, in the following, CEPC presents the projections using both the κ -framework and EFT approach. In the later part of this section, Higgs physics potential beyond coupling determination will be discussed.

11.1.7.1 Coupling fits in the κ -framework

The Standard Model makes specific predictions for the Higgs boson couplings to the SM fermions, $g(Hff; \text{SM})$, and to the SM gauge bosons $g(HVV; \text{SM})$.² In the κ -framework, the potential deviations are parameterized by

$$\kappa_f = \frac{g(Hff)}{g(Hff; \text{SM})}, \quad \kappa_V = \frac{g(HVV)}{g(HVV; \text{SM})}, \quad (11.8)$$

with $\kappa_i = 1$ indicating agreement with the SM prediction.

In addition to couplings which are present at tree level, the Standard Model also predicts effective couplings $H\gamma\gamma$ and Hgg , in terms of other SM parameters. Changes in the gluon and photon couplings can be induced by the possible shifts in the Higgs boson couplings described above. In addition, these couplings can also be altered by loop contributions from new physics states. Hence, these couplings will be introduced as two independent couplings, with their ratios to the SM predictions denoted as κ_γ and κ_g .

Furthermore, it is possible that the Higgs boson can decay directly into new physics particles. In this case, two type of new decay channels will be distinguished:

1. Invisible decay. This is a specific channel in which Higgs boson decay into invisible particles. This can be searched for and, if detected, measured.
2. Exotic decay. This includes all the other new physics channels. Whether they can be observed, and, if so, to what precision, depends sensitively on the particular final states. In one extreme, they can be very distinct and can be measured very well. In another extreme, they can be in a form which is completely swamped by the background. Whether postulating a precision for the measurement of the exotic decay or treating it as an independent parameter (essentially assuming it can not be measured directly) is an assumption one has to make. In the latter case, it is common to use the total width Γ_H as an equivalent free parameter.³

²For the discussion of coupling fits and their implications, “ H ” is used to denoted the 125 GeV Higgs boson.

³Total width is a very useful parameter in understanding and deriving parameter precisions in the κ -scheme.

In general, possible deviations of all Standard Model Higgs boson couplings should be considered. However, in the absence of obvious light new physics states with large couplings to the Higgs boson and other SM particles, a very large deviation ($> \mathcal{O}(1)$) is unlikely. In the case of smaller deviations, the Higgs boson phenomenology will not be sensitive to the deviations $[\kappa_e, \kappa_u, \kappa_d]$ and κ_s . Therefore, they will not be considered here and set to be their SM values.

The CEPC will not be able to directly measure the Higgs boson coupling to top quarks. A deviation of this coupling from its SM value does enter $H\gamma\gamma$ and Hgg amplitudes. However, this can be viewed as parametrized by κ_γ and κ_g already. Therefore, we will not include κ_t as an independent parameter. Hence, the following set of 10 independent parameters is considered:

$$\kappa_b, \kappa_c, \kappa_\tau, \kappa_\mu, \kappa_Z, \kappa_W, \kappa_\gamma, \kappa_g, \text{BR}_{\text{inv}}, \Gamma_H. \quad (11.9)$$

Several assumptions can be made that can lead to a reduced number of parameters (see also [8, 9]). It can be reduced to a 7-parameter set, by assuming lepton universality, and the absence of exotic and invisible decays (excluding $H \rightarrow ZZ^* \rightarrow \nu\bar{\nu}\nu\bar{\nu}$) [8, 10]:

$$\kappa_b, \kappa_c, \kappa_\tau = \kappa_\mu, \kappa_Z, \kappa_W, \kappa_\gamma, \kappa_g. \quad (11.10)$$

This is useful for hadron collider studies since it can not measure the Higgs boson total width with precision; it is more useful for models in which this assumption is satisfied.

There are some pros and cons of the κ -framework. κ_i s give a simple and intuitive parameterization of potential deviations. It has a direct connection with the observables shown in Table ???. It does cover a lot of possible modifications of the coupling. At the same time, κ -framework has its limitations. Strictly speaking, it should not be understood as modifying the SM renormalizable Lagrangian by a multiplicative factor. For instance, individual κ modifications violates gauge invariance. The higher order corrections in the κ framework is not easily defined. κ_i s do not summarize all possible effects of new physics neither. For example, in addition to the overall size, potential new physics can also introduce form factors which can change the kinematics of particles connected to a vertex. Manifestations of this effect will be seen in the discussion of the EFT approach. It is useful to pause here and compare with the EFT scheme introduced in detail in the next subsection. The EFT scheme relates κ_Z and κ_W , and further expance them into three different Lorentz structures. In addition, some of these higher dimensional HVV coupling are also in connection with κ_γ and anomalous trilinear gauge couplings. The current EFT scheme does not include important new degree of freedom BR_{inv} and Γ_H as independent parameters. Overall, κ -framework does capture the big picture of the capability of precision Higgs boson measurement at CEPC. It is useful as long as we understand its limitation.

The LHC and especially the HL-LHC will provide valuable and complementary information about the Higgs boson properties. For example, the LHC is capable of directly measure the ttH process [11, 12]. In addition, the LHC could use differential cross sections to differentiate top-loop contributions and other heavy particle-loop contributions to the Higgs boson to gluon coupling [13–16], and similarly to separate contributions from different operators to the Higgs boson to vector boson couplings [17]. For the purpose of the coupling fit in the κ -framework, the LHC with its large statistics, helps improving precision on rare processes such as Higgs to diphoton couplings. Note that a large portion of the systematics intrinsic to a hadron collider would be canceled by taking ratios

of measured cross sections. For example, combining the ratio of the rates $pp \rightarrow H \rightarrow \gamma\gamma$ and $pp \rightarrow H \rightarrow ZZ^*$ and the measurement of HZZ coupling at the CEPC can significantly improve the measurement of κ_γ . These are the most useful inputs from the LHC to combine with the CEPC. Similar studies of combination with the LHC for the ILC can be found in Refs. [18–22].

Table 11.4: Coupling measurement precision in percentage from the 7-parameter fit and 10-parameter fit described in the text for the CEPC, and corresponding results after combination with the HL-LHC. All the numbers refer to are relative precision except for $\text{BR}_{\text{inv}}^{\text{bsm}}$ of beyond standard model for which 95% CL upper limit are quoted respectively. Some entries are left vacant for the 7-parameter fit to stress them being dependent parameter under the fitting assumptions of the 7-parameter fit scheme.

	10-parameter fit		7-parameter fit	
	CEPC	+HL-LHC	CEPC	+HL-LHC
Γ_H	3.4	2.6	–	–
κ_b	1.7	1.3	1.6	1.2
κ_c	2.4	2.0	2.3	2.0
κ_g	1.7	1.3	1.7	1.3
κ_W	1.5	1.1	1.5	1.1
κ_T	1.6	1.2	1.6	1.2
κ_Z	0.25	0.25	0.16	0.16
κ_γ	4.3	1.7	4.2	1.7
κ_μ	8.6	5.0	–	–
$\text{BR}_{\text{inv}}^{\text{bsm}}$	0.31	0.31	–	–

The 10-parameter fit and the 7-parameter fit for CEPC with integrate luminosity of 5 ab^{-1} are shown in Table 11.4. In addition, the combinations with expectations (optimistically assuming no theoretical uncertainties) from the HL-LHC from Ref. [23] are shown in the same tables as well.⁴ We assume the HL-LHC will operate at 14 TeV center-of-mass energy and accumulate an integrated luminosity of 3000 fb^{-1} .

The CEPC Higgs boson properties measurements mark a giant step beyond the HL-LHC. First of all, in contrast to the LHC, a lepton collider Higgs factory is capable of measuring the absolute width and coupling strengths of the Higgs boson. A comparison with the HL-LHC is only possible with model dependent assumptions. One of such comparison is within the framework of a 7-parameter fit, shown in Fig. 11.9. Even with this set of restrictive assumptions, the advantage of the CEPC is still significant. The measurement of κ_Z is more than a factor of 10 better. The CEPC can also improve significantly on a set of channels which suffers from large background at the LHC, such as κ_b , κ_c , and κ_g . Note that this is in comparison with the HL-LHC projection with aggressive assumptions about systematics. Such uncertainties are typically under much better control at lepton colliders. Within this 7-parameter set, the only coupling which the HL-LHC can give

⁴We note here that the LHC and the CEPC have different sources of theoretical uncertainties, for detailed discussion, see Refs. [9, 10, 24–26].

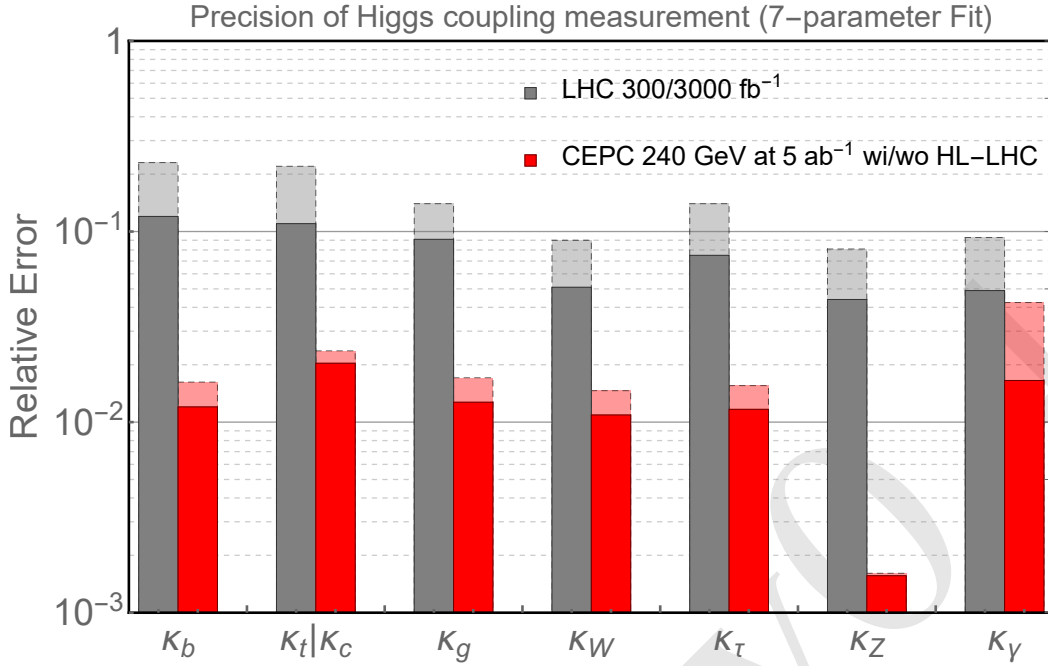

Figure 11.9: The 7 parameter fit result, and comparison with the HL-LHC [23]. The projections for the CEPC at 240 GeV with 5 ab⁻¹ integrated luminosity are shown. The CEPC results without combination with the HL-LHC input are shown with dashed edges. The LHC projections for an integrated luminosity of 300 fb⁻¹ are shown in dashed edges.

a competitive measurement is κ_γ , for which the CEPC's accuracy is limited by statistics. This is also the most valuable input that the HL-LHC can give to the Higgs boson coupling measurement at the CEPC, which underlines the importance of combining the results of these two facilities.

The direct search limit for BSM Higgs decay into invisibles $\text{BR}_{\text{inv}}^{\text{bsm}}$ is well motivated, in close connection to dark sectors. The CEPC with 5 ab⁻¹ can measure this to a high accuracy as 95% upper limit 0.31%, as shown in Table 11.4. At the same time, the HL-LHC can only manage a much lower accuracy 6-17% [10] and some improved analysis may reach 2-3.5% [27].

As discussed above, one of the greatest advantages of lepton collider Higgs boson factory is the capability of determining the Higgs boson coupling *model independently*. The projection of such a determination at the CEPC is shown in Fig. 11.10. The advantage of the higher integrated luminosity at a circular lepton collider is apparent. The CEPC has a clear advantage in the measure of κ_Z . It is also much stronger in κ_μ and BR_{inv} measurements.

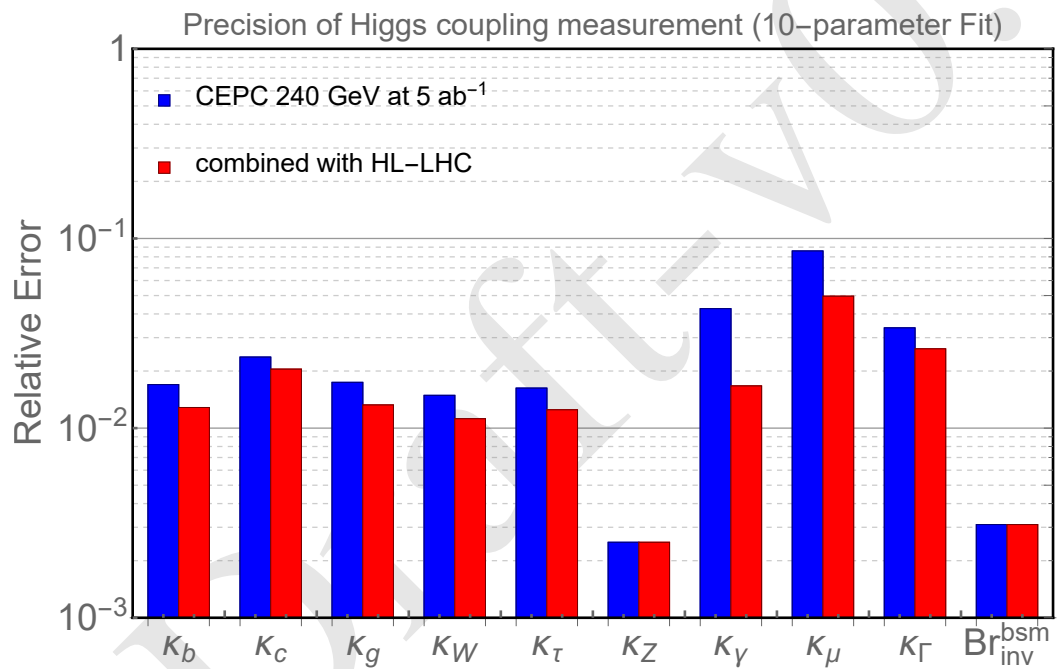

Figure 11.10: The 10 parameter fit result for CEPC at 240 GeV with 5 ab^{-1} integrated luminosity (blue) and in combination with HL-LHC inputs (red). All the numbers refer to are relative precision except for $\text{BR}_{\text{inv}}^{\text{bsm}}$ for which 95% CL upper limit are quoted respectively.

11.1.7.2 Effective-field-theory analysis

With the assumption that the new physics particles are heavier than the relevant energy of the Higgs factory, their effect can be characterized in the effective-field-theory (EFT) framework, in which higher dimensional operators supplement the Standard Model Lagrangian. Imposing baryon and lepton numbers conservations, all higher dimensional operators are of even dimension:

$$\mathcal{L}_{\text{EFT}} = \mathcal{L}_{\text{SM}} + \sum_i \frac{c_i^{(6)}}{\Lambda^2} \mathcal{O}_i^{(6)} + \sum_j \frac{c_j^{(8)}}{\Lambda^4} \mathcal{O}_j^{(8)} + \dots \quad (11.11)$$

The leading effects of new physics at the electroweak scale would be the dimension-six operators. To obtain robust constraints on the Wilson coefficients c_i , a global analysis is required which includes the contributions from all possible dimension-six operators. While a large number of dimension-six operators can be written down, only a subset of them contribute to the Higgs boson processes at leading order. Among these operators, some are much better constrained by other measurements. It is thus reasonable to focus on the operators that primarily contribute to the Higgs boson processes and reduce the parameter space by making appropriate assumptions, as done in many recent studies of EFT global analysis at future lepton colliders [22, 28–33]. Following these studies, the CP-violating operators as well as the ones that induce fermion dipole interactions are discarded in this analysis. At leading order, CP-violating operators do not have linear contributions to the rates of Higgs processes. While they do contribute to the angular observables at the leading order [34, 35], these operators are usually much better constrained by EDM experiments [36–38], though some rooms are still possible for the CP-violating couplings of Higgs boson to the heavy flavor quarks and leptons [39, 40]. The interference between the fermion dipole interactions with SM terms are suppressed by the fermion masses. The corresponding operators also generate dipole moments, which are stringently constrained especially for light fermions. For the operators that modify the Yukawa matrices, only the five diagonal ones that correspond to the top, charm, bottom, tau, and muon Yukawa couplings are considered, which are relevant for the Higgs boson measurements at CEPC.

Before presenting the projections, some brief comments on the EFT framework are in order. In comparison with the κ -framework, a significant advantage of the EFT framework is that it gives physical parameterizations of the new physics effect. EFT operators can be used directly in computations. It also allows natural inclusions of new observables, with possible correlations automatically taken into account. At the same time, the connections with experimental observables are less direct and intuitive. Sometimes, the EFT approach is referred to as model-independent. This is only accurate to a certain extent. At least, it assumes that there are no new light degrees of freedom. In practice, assumptions are often made to simplify the set of EFT operators, as also done here.

The electroweak precision observables are already tightly constrained by the LEP Z -pole and W mass measurements. The CEPC Z -pole run can further improve the constraints set by LEP, thanks to the enormous amount ($\sim 10^{11}$) of Z bosons that can be collected. The W mass can also be constrained within a few MeVs at CEPC even without a dedicated WW threshold run. Given that the expected precisions of the Z -pole observables and the W mass are much higher than the ones of Higgs boson observables, in the Higgs boson analysis, it is assumed that the former ones are perfectly constrained, which significantly simplifies the analysis. In particular, in a convenient basis all the contact

CEPC 240 GeV (5 ab^{-1})				
	uncertainty	correlation matrix		
		$\delta g_{1,Z}$	$\delta \kappa_\gamma$	λ_Z
$\delta g_{1,Z}$	1.3×10^{-3}	1	0.08	-0.90
$\delta \kappa_\gamma$	1.0×10^{-3}		1	-0.42
λ_Z	1.4×10^{-3}			1

Table 11.5: The estimated constraints on aTGCs from the measurements of the diboson process ($e^+e^- \rightarrow WW$) in the semi-leptonic channel at CEPC 240 GeV with 5 ab^{-1} data and unpolarized beams. All angular distributions are used in the fit. Only the statistical uncertainties of the signal events are considered, assuming a selection efficiency of 80%.

interaction terms of the form $hVf\bar{f}$ can be discarded since they also modify the fermion gauge couplings. Realistic Z -pole constraints have also been considered in recent studies [22, 31, 33], but certain assumptions (such as flavor-universality) and simplifications are made. Future studies with more general frameworks are desired to fully determine the impact of the Z -pole measurements on the Higgs boson analysis.

The measurements of the triple gauge couplings (TGCs) from the diboson process ($e^+e^- \rightarrow WW$) play an important role in the Higgs boson coupling analysis under the EFT framework. Focusing on CP-even dimension-six operators, the modifications to the triple gauge vertices from new physics can be parameterized by three anomalous TGC parameters (aTGCs), conventionally denoted as $\delta g_{1,Z}$, $\delta \kappa_\gamma$ and λ_Z [41, 42]. Among them, $\delta g_{1,Z}$ and $\delta \kappa_\gamma$ are generated by operators that also contribute to the Higgs boson processes. At 240 GeV, the cross section of $e^+e^- \rightarrow WW$ is almost two orders of magnitude larger than the one of the Higgsstrahlung process. The measurements of the diboson process thus provide strong constraints on the operators that generate the aTGCs. A dedicated study on the TGC measurements at CEPC is not available at the current moment. A simplified analysis is thus performed to estimate the precision reaches on the aTGCs. The results are shown in Table 11.5. The analysis roughly follows the methods in Refs. [30, 43]. Only the WW events in the semi-leptonic (electron or muon) channel are used, which have good event reconstructions and also a sizable branching fraction ($\approx 29\%$). In particular, the production polar angle, as well as the two decay angles of the leptonic W , can be fully reconstructed, which contain important information on the aTGCs. The two decay angles of the hadronic W can only be reconstructed with a two-fold ambiguity. A χ^2 fit of the three aTGC parameters to the binned distribution of all five angles is performed, from which the one-sigma precisions of the three aTGCs as well as the correlations among them are extracted. A signal selection efficiency of 80% is assumed. The effects of systematics and backgrounds are not considered, assuming they are under control after the selection cuts.

Under the assumptions specified above, the contributions to the Higgs boson and diboson processes from dimension-six operators consist of a total number of twelve degrees of freedom. While all non-redundant basis are equivalent, it is particularly convenient to choose a basis in which the twelve degrees of freedom can be mapped to exactly twelve operators, while the rest are removed by the assumptions. Two such bases are considered in our analysis, one is defined by the set of dimension-six operators in Table 11.6, the other is the so-called ‘‘Higgs basis,’’ proposed in Ref. [44]. In the Higgs basis, the param-

$\mathcal{O}_H = \frac{1}{2}(\partial_\mu H ^2)^2$	$\mathcal{O}_{GG} = g_s^2 H ^2 G_{\mu\nu}^A G^{A,\mu\nu}$
$\mathcal{O}_{WW} = g^2 H ^2 W_{\mu\nu}^a W^{a,\mu\nu}$	$\mathcal{O}_{y_u} = y_u H ^2 \bar{Q}_L \tilde{H} u_R \quad (u \rightarrow t, c)$
$\mathcal{O}_{BB} = g'^2 H ^2 B_{\mu\nu} B^{\mu\nu}$	$\mathcal{O}_{y_d} = y_d H ^2 \bar{Q}_L H d_R \quad (d \rightarrow b)$
$\mathcal{O}_{HW} = ig(D^\mu H)^\dagger \sigma^a (D^\nu H) W_{\mu\nu}^a$	$\mathcal{O}_{y_e} = y_e H ^2 \bar{L}_L H e_R \quad (e \rightarrow \tau, \mu)$
$\mathcal{O}_{HB} = ig'(D^\mu H)^\dagger (D^\nu H) B_{\mu\nu}$	$\mathcal{O}_{3W} = \frac{1}{3!} g \epsilon_{abc} W_\mu^{a\nu} W_\nu^b W_\rho^c \rho_\mu$

Table 11.6: A complete set of CP-even dimension-six operators that contribute to the Higgs and TGC measurements, assuming there is no correction to the Z -pole observables and the W mass, and also no fermion dipole interaction. For \mathcal{O}_{y_u} , \mathcal{O}_{y_d} and \mathcal{O}_{y_e} , only the contributions to the diagonal elements of the Yukawa matrices that corresponds to the top, charm, bottom, tau, and muon Yukawa couplings are considered.

eters are defined in the broken electroweak phase, and can be directly interpreted as the size of the Higgs couplings. Different from the original Higgs basis, this analysis follows Ref. [30], with the parameters associated with the Hgg , $H\gamma\gamma$ and $HZ\gamma$ vertices normalized to the SM one-loop contributions, and denoted as \bar{c}_{gg} , $\bar{c}_{\gamma\gamma}$ and $\bar{c}_{Z\gamma}$. The parameter $\bar{c}_{gg}^{\text{eff}}$ is further defined to absorb all contributions to the Hgg vertex, as shown in Eq. ???. These redefined parameters can be more conveniently interpreted as the precisions of the Higgs couplings analogous to those in the κ framework. The exact definitions of the Higgs basis and the translation to the basis in Table 11.6 can be found in the end of the section.

The estimated precisions of all the Higgs rate measurements in Section ?? (Table ??), along with the correlations among them, are included as inputs for the EFT global analysis. In addition, the angular observables of the channel $e^+e^- \rightarrow HZ$, $Z \rightarrow \ell^+\ell^-$, $H \rightarrow b\bar{b}$ are included, following the studies in Refs. [34, 35]. This channel is almost background-free after the selection cuts, with a signal selection efficiency of about 40%. For the TGC measurements, the results in Table 11.5 are used as inputs. The global χ^2 is obtained by summing over the χ^2 of all the measurements. Due to the high precision of the measurements, it is shown that for all observables, keeping only the linear terms of all EFT parameters gives a very good approximation [30]. This greatly simplifies the fitting procedure, as the total χ^2 can be written as

$$\chi^2 = \sum_{ij} (c - c_0)_i \sigma_{ij}^{-2} (c - c_0)_j, \quad \text{where} \quad \sigma_{ij}^{-2} \equiv (\delta c_i \rho_{ij} \delta c_j)^{-1}, \quad (11.12)$$

where c_i 's are the EFT parameters, c_0 's are the corresponding central values which are zero by construction, as the measurements are assumed to be SM-like. The one-sigma uncertainties δc_i and the correlation matrix ρ can be obtained from $\sigma_{ij}^{-2} = \partial^2 \chi^2 / \partial c_i \partial c_j$.

For comparison, the reaches of the LHC 14 TeV are also considered, with a total luminosities of 300 fb^{-1} or 3000 fb^{-1} , which are combined with the diboson ($e^+e^- \rightarrow WW$) measurements at LEP as well as the LHC 8 TeV Higgs measurements. For the LHC 14 TeV Higgs measurements, the projections by the ATLAS collaboration [23] are used, while the composition of each channel is obtained from Refs. [45–49]. The constraints from the LHC 8 TeV Higgs measurements and the diboson measurements at LEP are obtained directly from Ref. [50]. While the LHC diboson measurements could potentially improve the constraints on aTGCs set by LEP [51], they are not included in this analysis due to the potential issues related to the validity of the EFT [52, 53] and the TGC dominance assumption [54].

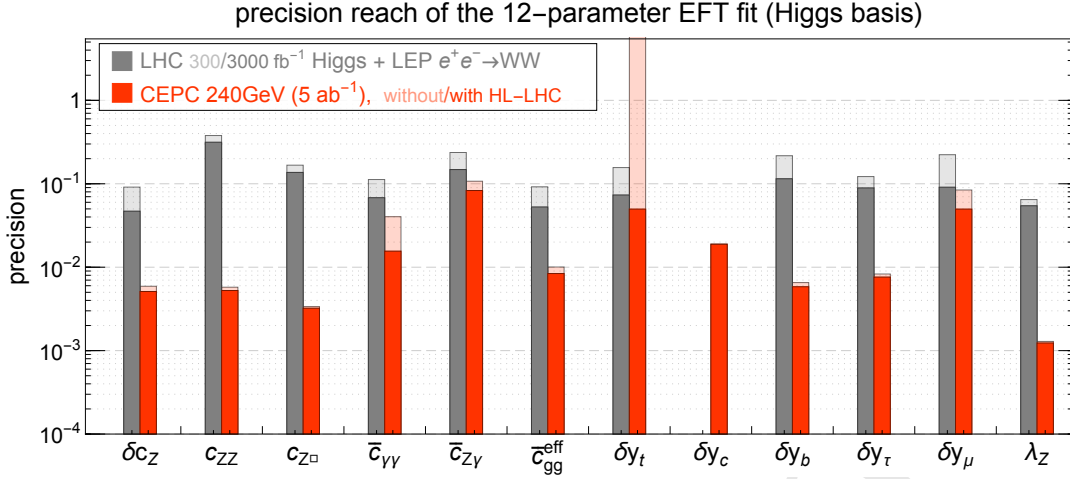

Figure 11.11: One-sigma precision reach of the twelve parameters in the Higgs basis. The first column shows the results from the LHC Higgs measurements with 300 fb⁻¹ (light shade) and 3000 fb⁻¹ (solid shade) combined with LEP diboson ($e^+e^- \rightarrow WW$) measurement. The second column shows the results from CEPC with 5 ab⁻¹ data collected at 240 GeV with unpolarized beam. The results from CEPC alone are shown in light shades, and the ones from a combination of CEPC and HL-LHC are shown in solid shades. δy_c is fixed to zero for the LHC fits.

The results of the 12-parameter fit at CEPC are shown in Fig. 11.11 for the Higgs basis and Fig. 11.12 for the basis in Table 11.6. The results from LHC Higgs measurements (both 300 fb⁻¹ and 3000 fb⁻¹) combined with LEP diboson measurements are shown in comparison. The results of the combination of CEPC with HL-LHC (3000 fb⁻¹) are also shown in addition to the ones of CEPC alone. In Fig. 11.11, the results are shown in terms of the one-sigma precision of each parameter. The LHC results are shown with gray columns with 300 fb⁻¹ (3000 fb⁻¹) in light (solid) shades, while the CEPC ones are shown with the red columns, with the CEPC-alone (combination with HL-LHC) results shown in light (solid) shades. In Fig. 11.12, the results are presented in terms of the reaches of $\Lambda/\sqrt{|c_i|}$ at 95% confidence level (CL), where Λ is the scale of new physics and c_i is the corresponding Wilson coefficient for each operator, defined in Eq. 11.11. Four columns are shown separately for LHC 300 fb⁻¹, LHC 3000 fb⁻¹, CEPC alone and CEPC combined with HL-LHC. The results of the global fits are shown with solid shades. The results from individual fits are shown with light shades, which are obtained by switching on one operator at a time with the rest fixed to zero.

It is transparent from Fig. 11.11 that CEPC provides very good reaches on the precisions of Higgs couplings, which are of one order of magnitude better than the ones at the LHC. For the parameters $\bar{c}_{\gamma\gamma}$, $\bar{c}_{Z\gamma}$ and δy_μ , the clean signal and small branching ratios of the corresponding channels ($H \rightarrow \gamma\gamma/Z\gamma/\mu\mu$) makes the HL-LHC precisions comparable with the CEPC ones. The combination with additional LHC measurements thus provides non-negligible improvements, especially for those parameters. It should be noted that, while δy_t modifies the Hgg vertex via the top loop contribution, CEPC alone could not discriminate it from the Hgg contact interaction (\bar{c}_{gg} in Eq. ??) obtained from integrating out a heavy new particle in the loop. The parameter \bar{c}_{gg}^{eff} absorbs both contributions and reflects the overall precision of the Hgg coupling. The combination with the LHC $t\bar{t}H$ measurements could resolve this flat direction. The CEPC measurements, in turn, could improve the constraint on δy_t set by the LHC by providing much better con-

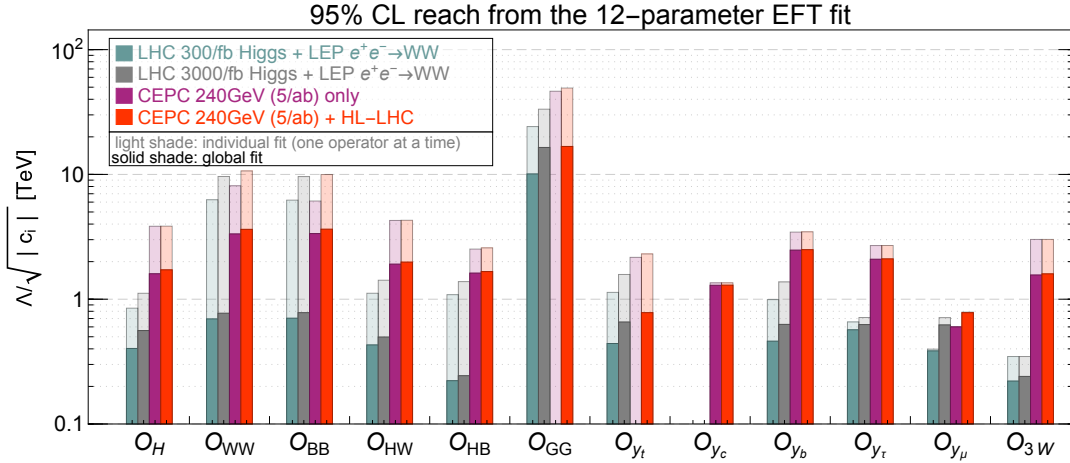

Figure 11.12: The 95% CL reach on $\Lambda/\sqrt{|c_i|}$ for the operators in the basis defined in Table 11.6. The first two columns show the results from LHC Higgs measurements with 300 fb^{-1} and 3000 fb^{-1} combined with LEP diboson ($e^+e^- \rightarrow WW$) measurement. The last two columns show the results from CEPC alone and the combination of CEPC and HL-LHC (3000 fb^{-1}). The results of the global fits are shown with solid shades. The results from individual fits (by switching on one operator at a time) are shown with light shades. δy_c is fixed to zero for the LHC fits.

straints on the other parameters that contribute to the $t\bar{t}H$ process. It should also be noted that the measurement of the charm Yukawa coupling is not reported in Ref. [23], while the projection of its constraint has a large variation among different studies and can be much larger than one [55–60]. Therefore, δy_c is fixed to be zero for the LHC-only fits, as treating δy_c as an unconstrained free parameter generates a flat direction in the fit which makes the overall reach much worse. The CEPC, on the other hand, provides excellent measurements of the charm Yukawa and can constrain δy_c to a precision of $\sim 2\%$.

Regarding the reaches of $\Lambda/\sqrt{|c_i|}$ in Fig. 11.12, it is also clear that CEPC has a significantly better performance than the LHC. If the couplings are naïvely assumed to be of order one ($c_i \sim 1$), the Higgs measurements at CEPC would be sensitive to new physics scales at multiple TeVs. While the individual reach for some of the operators at the LHC can be comparable to the ones at CEPC (e.g., O_{WW} and O_{BB} from the measurement of $H \rightarrow \gamma\gamma$), the reaches of CEPC are much more robust under a global framework thanks to its comprehensive measurements of both the inclusive HZ cross section and the exclusive rates of many Higgs decay channels. Operators O_{GG} and O_{yt} both contribute to the Hgg vertex. While the CEPC could provide strong constraints on either of them if the other is set to zero, they can only be constrained in a global fit if the $t\bar{t}h$ measurements at the LHC are also included. It is also important to note that the validity of EFT could be a potential issue for the LHC measurements [52]. Depending on the size of the couplings, the inferred bounds on the new physics scale Λ could be comparable with or even smaller than the energy scale probed by the LHC. The CEPC has a smaller center of mass energy and much better precisions, which ensures the validity of EFT for most new physics scenarios.

In Table 11.7 and Fig. ??, the numerical results of the global fit are presented for CEPC in terms of the one-sigma precisions of the 12 parameters and the correlations among them. The results assume an integrated luminosity of 5 ab^{-1} at 240 GeV with unpolarized beams, both without and with the combination of HL-LHC (3000 fb^{-1}) Higgs measurements. With both the one-sigma bounds and the correlation matrix, the corre-

sponding *chi-squared* can be reconstructed, which can be used to derive the constraints in any other EFT basis or any particular model that can be matched to the EFT. This offers a convenient way to study the reaches on new physics models, as detailed knowledge of the experimental measurements are not required.

Table 11.7: The one-sigma uncertainties for the 12 parameters from CEPC (240 GeV, 5 ab⁻¹) in the Higgs basis and the basis of dimension-six operators. For both cases, the upper (lower) row correspond to results without (with) the combination of the HL-LHC Higgs measurements.. Note that, without the $t\bar{t}h$ measurements, δy_t can not be constrained in a global fit, thus c_{GG} and c_{yt} can not be resolved.

In the EFT framework, it is explicitly assumed that the Higgs total width is the sum of all the widths of its SM decay channels. This is because the EFT expansion in Eq. 11.11 relies on the assumption that the new physics scale is sufficiently large, while any potential Higgs exotic decay necessarily introduces light BSM particles, thus in direct conflict with this assumption. One could nevertheless treat the Higgs total width as a free parameter in the EFT global fit and obtain an indirect constraint of it, as done in Ref. [22]. With this treatment, the CEPC could constrain the Higgs total width to a precision of 1.8% (1.7% if combined with HL-LHC). This result is significantly better than the one from the 10-parameter coupling fit in Table 11.4 (3.4%/2.6%). The improvement is mainly because the HWW and HZZ couplings are treated as being independent in the 10-parameter coupling fit, while in the EFT framework they are related to each other under gauge invariance and custodial symmetry. It should also be noted that the Higgs width determined using Eq. (11.4) and (11.7) explicitly assumes that the HWW and HZZ couplings are independent of the energy scale. Such an assumption is not valid in the EFT framework with the inclusion of the anomalous couplings.

11.1.7.3 The Higgs self-coupling

The Higgs boson self-coupling is a critical parameter governing the dynamics of the electroweak symmetry breaking. In the Standard Model, the Higgs trilinear and quadrilinear couplings are fixed once the values of the electroweak VEV and the Higgs mass are known. Any deviation from the SM prediction is thus clear evidence of new physics beyond the SM. The Higgs trilinear coupling is probed at the LHC with the measurement of the double-Higgs process, $pp \rightarrow HH$. Current bounds on the Higgs trilinear coupling is at the $\mathcal{O}(10)$ level, while the HL-LHC is expected to improve the precision to the level of $\mathcal{O}(1)$ [61]. The prospects for extracting the Higgs quadrilinear coupling are much less promising, even for a 100 TeV hadron collider [62].

To measure the double-Higgs processes at a lepton collider, a sufficiently large center of mass energy ($\gtrsim 400$ GeV) is required, which is likely to be achieved only at a linear collider. The CEPC, instead, can probe the Higgs trilinear coupling via its loop contributions to the single Higgs processes. This indirect approach nevertheless provides competitive reaches since the loop suppression is compensated by the high precision of

the Higgs measurements at CEPC [63]. With a precision of 0.5% on the inclusive HZ cross section at 240 GeV, the Higgs trilinear coupling can be constrained to a precision of 35%, assuming all other Higgs couplings that contributes to $e^+e^- \rightarrow HZ$ are SM-like.⁵ While this indirect bound is comparable to the direct ones at linear colliders, it relies on strong assumptions which are only applicable to some specific models. A more robust approach is to include all possible deviations on the Higgs couplings simultaneously and constrain the Higgs trilinear coupling in a global fit. The EFT framework presented in Section 11.1.7.2 is ideal for such an analysis. Under this framework, the one-loop contributions of the trilinear Higgs coupling to all the relevant Higgs production and decay processes are included, following Ref. [32]. The new physics effect is parameterized by the quantity $\delta\kappa_\lambda \equiv \kappa_\lambda - 1$, where κ_λ is the ratio of the Higgs trilinear coupling to its SM value,

$$\kappa_\lambda \equiv \frac{\lambda_3}{\lambda_3^{\text{sm}}}, \quad \lambda_3^{\text{sm}} = \frac{m_H^2}{2v^2}. \quad (11.13)$$

The global fit is performed simultaneously with $\delta\kappa_\lambda$ and the 12 EFT parameters in Section 11.1.7.2. The results are presented in Table 11.8. The results for HL-LHC are also shown, which were obtained in Ref. [64] under the same global framework. For CEPC 240 GeV, the one-sigma bound on $\delta\kappa_\lambda$ is around ± 3 , significantly worse than the 35% in the $\delta\kappa_\lambda$ -only fit. This is a clear indication that it is difficult to resolve the effects of $\delta\kappa_\lambda$ from those of other Higgs couplings. For HL-LHC, the reach on $\delta\kappa_\lambda$ is still dominated by the double-Higgs process. However, as a result of the destructive interferences among diagrams, the double-Higgs process at LHC could not constrain $\delta\kappa_\lambda$ very well on its positive side, even with the use of differential observables [65]. The combination of HL-LHC and CEPC 240 GeV thus provides a non-trivial improvement to the HL-LHC result alone, in particular for the two-sigma bound on the positive side, which is improved from $+6.1$ to $+2.8$. This is illustrated in Fig. 11.13, which plots the profiled χ^2 as a function of $\delta\kappa_\lambda$ for the two colliders.

bounds on $\delta\kappa_\lambda$	$\Delta\chi^2 = 1$	$\Delta\chi^2 = 4$
CEPC 240 GeV (5 ab^{-1})	$[-3.2, +3.3]$	$[-6.3, +6.7]$
HL-LHC	$[-0.9, +1.3]$	$[-1.7, +6.1]$
HL-LHC + CEPC 240 GeV	$[-0.8, +1.0]$	$[-1.5, +2.8]$
240 GeV (5 ab^{-1}) + 350 GeV (1.5 ab^{-1})	$[-0.48, +0.48]$	$[-0.96, +0.96]$

Table 11.8: The $\Delta\chi^2 = 1$ (one-sigma) and $\Delta\chi^2 = 4$ (two-sigma) bounds of $\delta\kappa_\lambda$ for various scenarios, obtained in a global fit by profiling over all other EFT parameters. The results for HL-LHC are obtained from Ref. [64].

It is also important to note that the reach on $\delta\kappa_\lambda$ in the global framework is significantly improved if an additional run at a higher energy, such as 350 GeV, is available. The global constraint on $\delta\kappa_\lambda$ is improved by almost one order of magnitude with 1.5 ab^{-1} data collected at the 350 GeV on top of the 5 ab^{-1} at 240 GeV. The usefulness of the 350 GeV run in discriminating different EFT parameters is thoroughly discussed in Ref. [30]. In

⁵ A better precision can be obtained by also using the exclusive channels, such as $\sigma(HZ) \times \text{BR}(H \rightarrow b\bar{b})$, but would require an even stronger assumption that all Higgs couplings contributing to the branching ratios are also SM-like except the Higgs trilinear coupling.

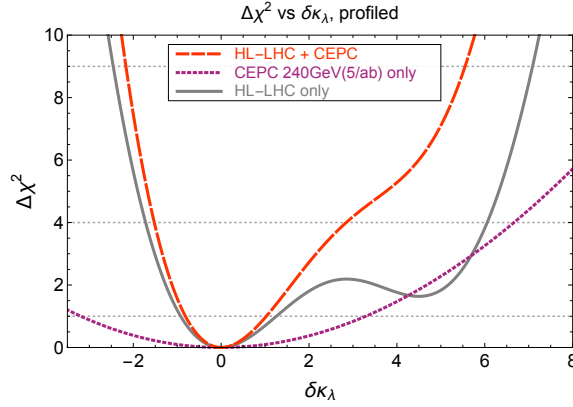

Figure 11.13: Chi-square as a function of $\delta\kappa_\lambda$ after profiling over all other EFT parameters for HL-LHC, CEPC and their combination.

addition, it was pointed out in Refs. [32, 63] that the sensitivity of $\sigma(HZ)$ to $\delta\kappa_\lambda$ is maximized near the HZ threshold and decreases as the center of mass energy increases – a feature not exhibited by the other EFT parameters. Measuring $e^+e^- \rightarrow HZ$ at two different energies is thus particularly helpful in discriminating $\delta\kappa_\lambda$ with other EFT parameters.

11.1.7.4 Higgs and top couplings

Interactions of the Higgs boson with the top quark are widely viewed as a window to new physics beyond the Standard Model. Parameterizing effects of new physics in terms of dimension-six gauge-invariant operators modifying the Higgs-top interactions [66, 67], the Higgs top couplings physics potential at CEPC can be evaluated [68–71]. This EFT basis enlarges the Higgs EFT considered above. Moreover, the CP violation effects in the third generation Yukawas can be reflected as the complexity of the Wilson coefficients of operator \mathcal{O}_{y_t} and \mathcal{O}_{y_b} ,

$$\Delta y_t = y_t^{\text{SM}} \left(\Re[C_{y_t}] \frac{v^3}{2m_t \Lambda^2} + i \Im[C_{y_t}] \frac{v^3}{2m_t \Lambda^2} \right) \quad (11.14)$$

$$\Delta y_b = y_b^{\text{SM}} \left(\Re[C_{y_b}] \frac{v^3}{2m_b \Lambda^2} + i \Im[C_{y_b}] \frac{v^3}{2m_b \Lambda^2} \right). \quad (11.15)$$

In this section, the effect of introducing CP phases in the Yukawa operators in Higgs physics are discussed. For more detailed discussion on a complete set of Higgs and Top operators, see Ref. [68]. The dominant sources of constraints are from $H \rightarrow \gamma\gamma$ and $H \rightarrow gg$ for \mathcal{O}_{y_t} , and $H \rightarrow gg$ and $H \rightarrow b\bar{b}$ for \mathcal{O}_{y_b} . Given that $H \rightarrow gg$ measurements are sensitive to both operators, a joint analysis of \mathcal{O}_{y_t} and \mathcal{O}_{y_b} will yield a significantly different result comparing to individual operator analysis. A joint analysis for these two operators in terms of Yukawa coupling strengths and the associated CP phases is performed at CEPC. The important physics cases for such considerations are highlighted.

In Fig. 11.14 constraints on the top and bottom Yukawa coupling strengths and their CP phases are presented in the left panel and right panel, respectively. The 68% and 95% exclusion bands are shown in solid and dashed lines. The limits for CEPC are shown in *bright* black and magenta lines for individual operator analysis and the *bright* green and yellow shaded regions representing the 68% and 95% allowed parameter space, respectively. The *dimmed* thick black curves represent the results after turning on both operators

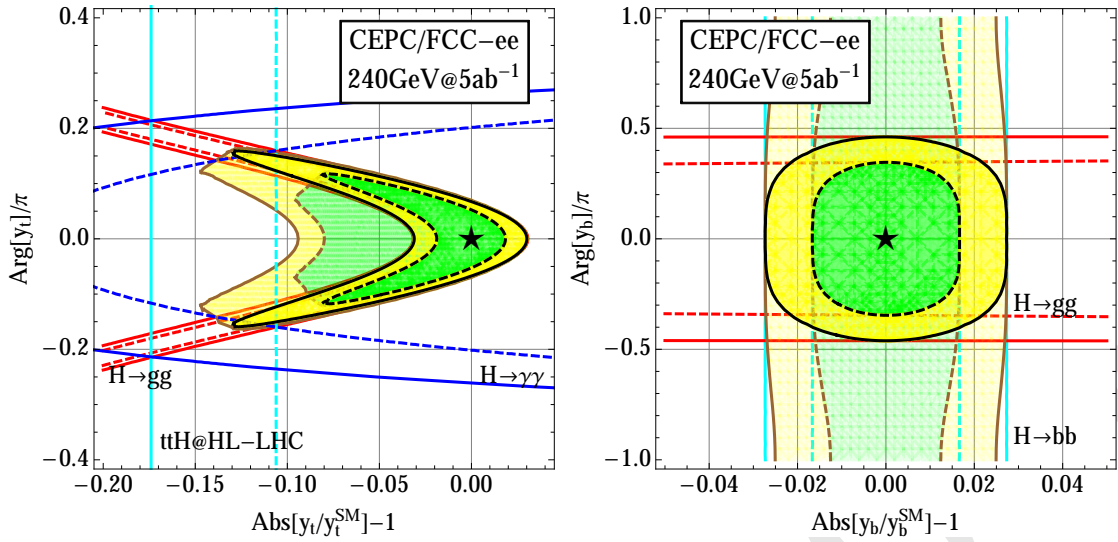

Figure 11.14: Results for analysis on C_{y_t} and C_{y_b} in the projected allowed regions for modification to top and bottom Yukawa couplings in magnitude and CP phase at 68% and 95% confidence level. The combined results for CEPC are shown in black curves. The source of individual constraints for the single operator analysis are labeled correspondingly. For a joint analysis of simultaneous appearance of both \mathcal{O}_{y_t} and \mathcal{O}_{y_b} operators, the results for CEPC are shown in the enlarged yellow (95%) and green regions (68%) with thick brown boundary lines.

\mathcal{O}_{tH} and \mathcal{O}_{bH} at the same time, using a profile-likelihood method profiling over other parameters. Furthermore, in the left panel the cyan band represents constraints from HL-LHC $t\bar{t}H$ measurements, red bands are constraints from CEPC $H \rightarrow gg$ measurements and blue bands are constraints from CEPC $H \rightarrow \gamma\gamma$ measurements. Similarly in the right panel, the cyan bands are constraints from $H \rightarrow b\bar{b}$ and the red bands are constraints from $H \rightarrow gg$ at CEPC.

The left panel of Fig. 11.14 shows that the expected sensitivity on the modification in the magnitude of top Yukawa is at around $\pm 3\%$ for the single operator analysis, which is relaxed to $[-9.5\%, +3\%]$ for the joint analysis allowing the bottom Yukawa and the associated CP phase to vary freely, in the case of zero CP phase in the top Yukawa. The phase of the top Yukawa could be constrained to be $\pm 0.16\pi$. The constraints on the phase of the top Yukawa is driven by the $H \rightarrow \gamma\gamma$ measurements, where a sizable phase shift will enlarge the Higgs to diphoton rate via reducing the interference with SM W -loop. The constraints on the magnitude of the top Yukawa modification is driven by the $H \rightarrow gg$ measurements due to the dominant contribution to $H \rightarrow gg$ being from top-loop. Note that constraints from $H \rightarrow gg$ measurement is not entirely vertical, this is a result of the different sizes of the top-loop contribution to $H \rightarrow gg$ through scalar and pseudoscalar couplings. Similarly, as shown in the right panel of Fig. 11.14 for the bottom Yukawa magnitude modification, the constraint is $\pm 2.5\%$ and, for the bottom Yukawa CP phase, the constraints changes from $\pm 0.47\pi$ to no constraint for simultaneous modification to top Yukawa.

11.1.8 Tests of Higgs boson spin/CP

Need further editing...

The CP parity of a Higgs boson, and more generally its anomalous couplings to gauge bosons in the presence of BSM physics, can be measured at the CEPC based on the $e^+e^- (\rightarrow Z^*) \rightarrow ZH \rightarrow \mu^+\mu^-b\bar{b}$ process. It is convenient to express the anomalous coupling measurements in terms of physical quantities of effective fractions of events of the anomalous contribution relative to the SM predictions as detailed in Refs. [72–74], which are invariant under independent re-scalings of all couplings.

Two of the anomalous HZZ coupling measurements are of particular interest at the CEPC: the fraction of the high-order CP -even contribution due to either SM contribution or new physics, f_{a2} , and the fraction of a CP -odd contribution due to new physics, f_{a3} . The following two types of observables can be used to measure these anomalous couplings of the Higgs bosons.

1. The dependence of the $e^+e^- \rightarrow Z^* \rightarrow ZH$ cross section on \sqrt{s} is different for different CP property of the Higgs boson [74]. Therefore, measurements of the cross section at several different energies will yield useful information about anomalous HZZ couplings. However this has non-trivial implications to the accelerator design and is not included in this study as a single value of \sqrt{s} assumed for the CEPC operating as a Higgs boson factory.
2. Angular distributions, $\cos \theta_1$ or $\cos \theta_2$ and Φ as defined in Ref. [74]. These angles are also sensitive to interference between CP -even and CP -odd couplings. In particular forward-backward asymmetry with respect to $\cos \theta_1$ or $\cos \theta_2$ and non-trivial phase in the Φ distributions can lead to an unambiguous interpretation of CP violation.

To estimate the sensitivities on the anomalous couplings, a maximum likelihood fit [74] is performed to match observed three-dimensional angular distributions to theory predictions including signal and background processes. In this likelihood fit, the signal probability density functions are from analytical predictions that are validated using a dedicated MC program, the JHU generator [72, 73], which incorporates all the anomalous couplings, spin correlations, interference of all contributing amplitudes. The background probability density function is modeled from simulation based on $e^+e^- \rightarrow ZZ \rightarrow \ell^+\ell^-b\bar{b}$ process in Madgraph. The total integrated luminosity is assumed to be 5 ab^{-1} .

Several thousand statistically-independent experiments are generated and fitted to estimate the sensitivity to f_{a2} and f_{a3} , defined as the smallest values that can be measured with 3σ away from 0. All other parameters in the fit, including the number of expected signal and background events, are fixed. Figure 11.15 shows precision on f_{a2} and f_{a3} obtained with generated experiments. The expected sensitivity on f_{a2} and f_{a3} are 0.018 and 0.007 respectively.

The sensitivities of f_{a2} and f_{a3} are then converted to the equivalent parameters defined for the on-shell $H \rightarrow ZZ^*$ decays, f_{a2}^{dec} and f_{a3}^{dec} , in order to compare with the sensitivities from other experiments as described in Ref. [74]. The corresponding sensitivities of f_{a2}^{dec} and f_{a3}^{dec} are 2×10^{-4} and 1.3×10^{-4} respectively. The much smaller values in the $f_{a2,3}^{\text{dec}}$ are due to the much larger $m_{Z^*}^2$ in the $Z^* \rightarrow ZH$ production compared to the value in the $H \rightarrow ZZ^*$ decays. A simultaneous fit of f_{a2} and f_{a3} can also performed with the 68% and 95% confidence level contours shown in Figure 11.15.

Compared to the ultimate sensitivity from HL-LHC experiments as shown in Ref. [74], the sensitivities in the f_{a2} and f_{a3} at the CEPC are a factor of 300 and 3 better. Further improvements can be achieved by exploring kinematics in the $H \rightarrow b\bar{b}$ decays, including

other Z decay final states, and combining with the overall cross-section dependence of the signal with a threshold scan in \sqrt{s} .

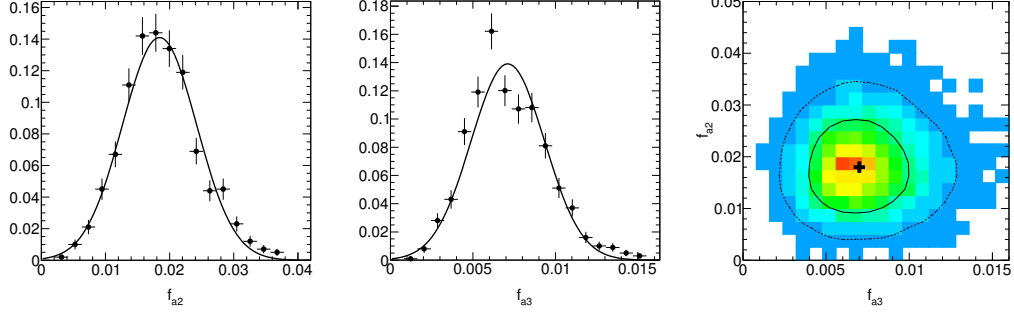

Figure 11.15: Distribution of fitted values of f_{a2} and f_{a3} in a large number of generated experiments. In the left and middle plots, only the parameter shown is floated. Other parameters are fixed to SM expectations. Right plot: simultaneous fit of non-zero f_{a2} and f_{a3} , with 68% and 95% confidence level contours shown. **Keep the right plot only?**

11.1.9 Summary

To do: need to actually summarize what is described above.

The Higgs boson is responsible for the electroweak symmetry breaking. It is the only fundamental scalar particle in the Standard Model observed so far. The discovery of such a particle at the LHC is a major breakthrough on both theoretical and experimental fronts. However, the Standard Model is likely only an effective theory at the electroweak scale. To explore potential new physics at the electroweak scale and beyond, complementary approaches of direct searches at the energy frontier as well as precision measurements will be needed. The current LHC and the planned HL-LHC have the potential to significantly extend its new physics reach and to measure many of the Higgs boson couplings with precision of a few percents.

However, many new physics models predict Higgs boson coupling deviations at the sub-percent level, beyond those achievable at the LHC. The CEPC complements the LHC and will be able to study the properties of the Higgs boson in great details with unprecedented precision. Therefore it is capable of unveiling the true nature of this particle. At the CEPC, most Higgs boson couplings can be measured with precision at a sub-percent level. More importantly, the CEPC will be able to measure many of the key Higgs boson properties such as the total width and decay branching ratios model independently, greatly enhancing the coverage of new physics searches. Furthermore, the clean event environment of the CEPC will allow the detailed study of known decay modes and the identification of potential unknown decay modes that are impractical to test at the LHC.

This paper provides a snapshot of the current studies, many of them are ongoing and more analyses are needed to fully understand the physics potential of the CEPC. Nevertheless, the results presented here have already built a strong case for the CEPC as a Higgs factory. The CEPC has the potential to “undress” the Higgs boson as what the LEP has done to the Z boson, and shed light on new physics.

Draft-V0.4

11.2 W, Z measurements at the CEPC

With high production cross sections and large integrated luminosity, the CEPC will reach a new level of precision for measurements of the properties of the W and Z bosons. Precise measurements of the W and Z boson masses, widths, and couplings are critical to test the consistency of the SM [1]. In addition, many BSM models predict new couplings of the W and Z bosons to other elementary particles. Precise electroweak measurements performed at the CEPC could discover deviations from the SM predictions and reveal the existence of new particles that are beyond the reach of current experiments.

Significant improvements are expected from the CEPC measurements. Table 11.9 lists the expected precision from CEPC compared to achieved precisions from the LEP experiments for various measurements. Details about the estimation of these uncertainties are described in this section.

Table 11.9: The expected precision in a selected set of EW precision measurements in CEPC and the comparison with the precision from LEP experiments. The CEPC accelerator running mode and total integrated luminosity expected for each measurement are also listed. Depending on detector solenoid field during Z pole operation, the integrated luminosity varied from $8ab^{-1}$ to $16ab^{-1}$.

Observable	LEP precision	CEPC precision	CEPC runs	$\int \mathcal{L}$ needed in CEPC
m_Z	2 MeV	0.5 MeV	Z threshold scan	$8ab^{-1} - 16ab^{-1}$
$A_{FB}^{0,b}$	1.7%	0.1%	Z threshold scan	$8ab^{-1} - 16ab^{-1}$
$A_{FB}^{0,\mu}$	7.7%	0.3%	Z threshold scan	$8ab^{-1} - 16ab^{-1}$
$A_{FB}^{0,e}$	17%	0.5%	Z threshold scan	$8ab^{-1} - 16ab^{-1}$
$\sin^2 \theta_W^{\text{eff}}$	0.07%	0.001%	Z threshold scan	$8ab^{-1} - 16ab^{-1}$
R_b	0.3%	0.02%	Z pole	$8ab^{-1} - 16ab^{-1}$
R_μ	0.2%	0.01%	Z pole	$8ab^{-1} - 16ab^{-1}$
N_ν	1.7%	0.05%	ZH runs	$5.6ab^{-1}$
m_W	33 MeV	2-3 MeV	ZH runs	$5.6ab^{-1}$
m_W	33 MeV	1 MeV	WW threshold	$2.6ab^{-1}$

11.2.1 Z pole measurements

The CEPC offers the possibility of dedicated low-energy runs at the Z pole for at least two years with a high instant luminosity ($1.6 - 3.2 \times 10^{35} \text{cm}^{-2}\text{s}^{-1}$). The expected integrated luminosity for CEPC Z pole runs is more than 8ab^{-1} , and it is expected to produce about 10^{12} Z bosons (Tera- Z).

These runs allow high precision electroweak measurements of the Z boson decay partial widths, e.g. the parameters $R_b = \Gamma_{Z \rightarrow b\bar{b}}/\Gamma_{\text{had}}$ and $R_\ell = \Gamma_{\text{had}}/\Gamma_{Z \rightarrow \ell\bar{\ell}}$. (Notice that R_ℓ is defined as the ratio to any *one* charged lepton flavor, assuming lepton universality, not the ratio to the sum of all lepton flavors.) It would also perform high precision measurements of the forward-backward charge asymmetry (A_{FB}), the effective weak mix-

ing angle ($\sin^2 \theta_W^{\text{eff}}$), number of light neutrino species (N_ν), and the mass of the Z boson (M_Z). It is also possible to perform some measurements with the Z boson without these dedicated low-energy runs near or at the Z pole. For example, the direct measurement of the number of light neutrino species can be performed in ZH runs at 240 GeV.

11.2.1.1 R_b

The width of the Z boson to each of its decay channels is proportional to the square of the fundamental Z -fermion couplings. The partial width R_b is sensitive to electroweak radiative corrections from new physics particles. For example, the existence of the scalar tops or charginos in supersymmetry could lead to a visible change of R_b from the SM prediction.

Precise measurements of R_b have been made by LEP collaborations [2–6] and by the SLD collaboration [7] at SLAC using hadronic Z events.

Decays of b -hadrons were tagged using tracks with large impact parameters and/or reconstructed secondary vertices, complemented by event shape variables. The combination of LEP and SLD measurements yields a value of 0.21629 ± 0.00066 for R_b . The relative statistical uncertainty of R_b is above 0.2%, and systematic uncertainty is about 0.2%.

A precision of 0.05% can be achieved for the measurement of R_b at CEPC, and it will improve the current precision in experimental measurement by one order of magnitude. The statistical uncertainty improves by two order of magnitude and the systematic uncertainties will also reduce. The main systematic uncertainty is the uncertainty due to hemisphere tag correlations in $Z \rightarrow b\bar{b}$ events (0.05%). The uncertainty due to hemisphere tag correlations will be reduced to a level of 0.05% due to the expected improvement in the b -tagging performance of the CEPC detector. The improvement of b -tagging efficiency is important to reduce this corrections, and this correlation becomes irrelevant in the limit of 100% b -tagging efficiency. Due to that fact that a next-generation vertex detector will be used in the CEPC detector, the b -tag efficiency is expected to be around 70% with a b -jet purity of 95% as shown in Fig. ??, which is about 15%-20% higher than the efficiency in than previous measurements. The uncertainty due to hemisphere tag correlations can be reduce to 0.05% level, which is a factor of four lower than previous measurements.

11.2.1.2 The partial decay width of $Z \rightarrow \mu^+ \mu^-$

The $\mu^+ \mu^-$ channel provides the cleanest leptonic final state. Combining the measurements from all four LEP experiments [8–11], the overall uncertainty of R_μ is 0.2%. The statistical uncertainty of R_μ is 0.15%.

A precision of 0.01% can be achieved at the CEPC. The main systematic is the uncertainty of photon energy scale in the $Z \rightarrow \mu^+ \mu^- \gamma$ process. About 2% of the $Z \rightarrow \mu^+ \mu^-$ sample are classified as $Z \rightarrow \mu^+ \mu^- \gamma$ events with a photon detected in ECAL. For this class of events, the most critical cut is that on the difference between the expected and measured photon energy ($|E_\gamma^{\text{expected}} - E_\gamma^{\text{measured}}| < 5\sigma_\gamma$), which is very efficient in removing the $Z \rightarrow \tau\tau$ background. The

The energy resolution in the EM calorimeter of the CEPC detector is expected to be $16\%/\sqrt{E}$, which is significantly better than the resolution in previous measurements. Therefore, the uncertainty due to photon energy scale and resolution in $Z \rightarrow \mu^+ \mu^- \gamma$ process can be reduced to 0.01%. The main challenge in this measurement is to reduce the systematics due to QED ISR events. More detailed studies of radiative events in Z

threshold scan runs are expected. Benefitting from high statistics in Z threshold scan runs, the source of uncertainty can be reduced to a level of 0.03%.

11.2.1.3 The forward-backward asymmetry A_{FB}^b at the Z pole

The measurement of the forward-backward asymmetry in $e^+e^- \rightarrow b\bar{b}$ events at the Z pole, $A_{FB}^{b,0}$, gives an important test of the Standard Model. $A_{FB}^{b,0}$ offers the most precise determination of the weak mixing angle. The measurements have been made at SLD and LEP experiments [12–16].

$Z \rightarrow b\bar{b}$ events were identified by tagging two b jets. Each event was divided into forward and backward categories by the plane perpendicular to the thrust axis which contains the interaction point. The combination of the LEP and SLD measurements gives a measured value of $A_{FB}^{b,0} = 0.1000 \pm 0.0017$. The statistical uncertainty is 1.2% and the main systematic uncertainties come from hemisphere tag correlations for b events (1.2%), tracking resolution and vertex detector alignment (0.8%), charm physics modeling (0.5%), and QCD and thrust axis correction (0.7%).

A precision of 10^{-4} can be achieved for the measurement of $A_{FB}^{b,0}$ at the CEPC, improving the current precision by more than a factor of 10. The expected statistical uncertainty is at a level of 0.05%. The uncertainty due to hemisphere tag correlations for b events can be reduced to 0.1% due to high b -tagging efficiency. The uncertainty due to charm physics modeling can be reduced to 0.05% by choosing a tighter b -tagging working point. The uncertainty due to tracking resolution and vertex detector alignment can be reduced to 0.05%. The expected tracking momentum resolution in the CEPC detector is $\sigma/p_T = 2 \times 10^{-4} \times p_T + 0.005$, which is 10 times better than the resolutions of the LEP detectors. The uncertainty due to QCD and thrust axis correction can be reduced to 0.1% due to at least 10 times better granularity in the CEPC calorimeters. Overall, the expected systematics at CEPC measurement can be reduced to a level of 0.15%.

11.2.1.4 The prospects for the effective weak mixing angle measurement

The weak mixing angle $\sin^2 \theta_W^{\text{eff}}$ is a very important parameter in the electroweak theory of the SM. It is the only free parameter that fixes the relative couplings of all fermions to the Z . It describes the rotation of the original W^0 and B^0 vector boson states into the observed γ and Z bosons as a result of spontaneous symmetry breaking. The weak mixing angle is very sensitive to electroweak radiative corrections, and it can be used to perform a precise test of the SM theory. Furthermore, if there is any new heavy gauge boson Z' , the weak mixing angle is expected to deviate from the SM prediction due to the contribution from physics in loop corrections. Therefore $\sin^2 \theta_W^{\text{eff}}$ is very sensitive to new physics as well.

The centre-of-mass energy dependence of the forward-backward asymmetry arises from the interference of the Z boson with the virtual photon and thus depends on $\sin^2 \theta_W^{\text{eff}}$. In other words, the effective weak mixing angle can be extracted by studying the \sqrt{s} dependence of the forward-backward asymmetry.

The effective weak mixing angle measurement has been performed in LEP using $Z \rightarrow b\bar{b}$ events and $Z \rightarrow \ell^+\ell^-$ events. The forward-backward asymmetry A_{FB} in one Z -pole dataset and two off Z -pole datasets ($\sqrt{s} = 89.4$ GeV, $\sqrt{s} = 93.0$ GeV) are used to extract $\sin^2 \theta_W^{\text{eff}}$. The current experimental result is $\sin^2 \theta_W^{\text{eff}} = 0.23153 \pm 0.00016$. $Z \rightarrow b\bar{b}$ events were identified by tagging two b jets. The main uncertainty includes uncertainty on

the A_{FB}^b measurement as described in Sec. 11.2.1.3. and the statistical uncertainty in off Z -pole datasets.

Both Z -pole and off Z -pole runs are needed to perform the effective weak mixing angle measurement at the CEPC. The Z off-peak runs are expensive, therefore we need to optimize the integrated luminosity for off-peak runs. In order to improve the precision of $\sin^2 \theta_W^{\text{eff}}$ by a factor of 3, the required CEPC integrated luminosity for Z -pole runs are $8 - 16 \text{ ab}^{-1}$ and at least $2 - 4 \text{ ab}^{-1}$ integrated luminosity is needed for off Z -pole runs. The expected precision of effective weak mixing angle measurement in CEPC using $Z \rightarrow b\bar{b}$ events is expected to be 0.02%.

11.2.1.5 Z mass measurement

The mass m_Z is a fundamental parameter in the SM and was determined with an overall uncertainty of 2 MeV by four LEP experiments. The mass scan around the Z peak was performed from 88 GeV to 94 GeV. The Z mass was measured by a combined fit to the hadronic and leptonic cross sections in the on-peak and off-peak datasets. Most of the m_Z information is extracted from the off-peak runs. Taking the OPAL measurement as one example, six off-peak datasets were used to complete the m_Z scan. The main uncertainty of m_Z includes the statistical uncertainty ($1 \text{ MeV}/c^2$), and the LEP beam energy (about $1 \text{ MeV}/c^2$).

A precision of 0.5 MeV can be achieved in CEPC measurement. The mass scan around the Z peak is the key for improving m_Z measurements.

The LEP measurement was limited by the statistics in their off-peak runs, therefore the luminosity in Z off-peak runs plays an important role in the m_Z measurement. We propose six off-peak runs and one on-peak run in CEPC Z mass scan, as listed in Table ?? . The expected m_Z uncertainty in CEPC due to statistics is about 0.1 MeV.

Another important systematic is beam momentum scale uncertainty. The beam momentum uncertainty in the CEPC accelerator is expected to be accurate to the 10 ppm level, which is about five times better than LEP. The uncertainty on m_Z due to the uncertainty on the beam energy can be reduced to less than 0.5 MeV.

Hadronic decay channels of the Z events are also expected to be used to measure m_Z since the leptonic decay channels suffer from low statistics. The uncertainty due to jet energy scale and resolution results in about 0.1 MeV in the m_Z measurement.

11.2.1.6 Neutrino species counting

Two different methods have been used to determine the number of neutrino species (N_ν) at LEP.

The first method is an indirect method using the analysis of the Z lineshape, and it uses the data collected by the Z threshold scan runs. The second method is a direct measurement, which is based on the measurement of the cross section for the radiative process $e^+e^- \rightarrow \nu\nu\gamma$. The second method at CEPC is supposed to use the ZH runs.

These two methods use different theoretical inputs from the Standard Model and also use completely different datasets, therefore they are independent and complementary. The sensitivity to new physics will be different for these two methods. In the direct method, one can measure N_ν as a function of \sqrt{s} . This is very sensitive to new physics at high energy scales. Possible contributions include WIMP dark matter particles, and other weakly coupled particles such as exotic neutrinos, gravitinos, or KK gravitons in theories

with large extra dimensions. Thus, when we refer to the number of neutrino species, we actually include any number of possible invisible particles other than neutrinos.

Indirect method from Z line shape The indirect method assumed all contributions from invisible channels are coming from the $Z \rightarrow \nu\bar{\nu}$. This method used the analysis of Z line-shape, subtracting the visible partial widths of the hadrons (Γ_{had}), and the partial widths of the leptons (Γ_ℓ) from the total width Γ_Z . The invisible width Γ_{inv} can be written as:

$$\Gamma_{\text{inv}} = N_\nu \Gamma_\nu = \Gamma_Z - \Gamma_{\text{had}} - 3\Gamma_\ell. \quad (11.16)$$

We take as our definition of the number of neutrinos $N_\nu = \Gamma_{\text{inv}}/\Gamma_\nu$, i.e. the ratio of the invisible width to the Standard Model expectation for the partial width to a single neutrino species.

Using the input from SM model, we can rewrite equation 11.16 as the following:

$$N_\nu = \frac{\Gamma_\ell}{\Gamma_\nu} \left(\sqrt{\frac{12\pi R_\ell}{M_Z^2 \sigma_{\text{had}}^0}} - R_\ell - 3 \right). \quad (11.17)$$

As shown in equation 11.17, the precision of N_ν depends on the the lepton partial width R_ℓ measurement, the Z mass measurement, and the hadronic cross section of the Z boson on its mass peak (σ_{had}^0). The precision of σ_{had}^0 gives the largest impact to N_ν measurement, and it is very sensitive to the precision of the luminosity. Therefore the precise luminosity measurement is the key to determine N_ν .

Precise measurements of N_ν have been made by LEP collaborations, and they obtained a precision of 0.27% using this indirect method. The main systematics of the N_ν measurement is coming from the uncertainty of luminosity (0.14%) and the theory uncertainty in the predicted cross section of the small angle Bhabha process (0.11%).

The precision of 0.1% in N_ν measurement with the indirect method can be achieved in CEPC measurement, which improves the current precision by a factor of three. Benefitting from the recent development of luminosity detector technology, the uncertainty due to luminosity can be reduced to 0.05%. The uncertainty from the small angle Bhabha process can be reduced to 0.05% due to recent progress in studying this process.

Direct method using $e^+e^- \rightarrow \nu\bar{\nu}\gamma$ events The most precise direct N_ν measurements at LEP were carried out by the L3 collaboration and Delphi collaboration. By combining the direct measurements at LEP, the current experimental result is $N_\nu = 2.92 \pm 0.05$. The statistical uncertainty of N_ν in the previous measurement is 1.7%. The main systematic uncertainty from the L3 measurement includes the uncertainty in single photon trigger efficiency (0.6%), and photon identification efficiency (0.3%), and the uncertainty in identifying the converted photons (0.5%).

A precision of 0.2% can be achieved for the direct measurement of N_ν at CEPC, and it will improve the current precision by a factor of 10. Due to the excellent performance of the CEPC inner tracker, the uncertainty due to converted photons' selection efficiency is expected to be negligible. The granularity of the CEPC EM calorimeter is expected to be 10 to 100 times better than the detectors at LEP. Therefore photons can be identified with high purity with loose EM shower shape based selection. The uncertainty of photon efficiency can be reduced to less than 0.05%.

11.2.2 Measurement of the W boson mass

In e^+e^- collisions, W bosons are mainly produced in pairs, through the reaction $e^+e^- \rightarrow W^+W^-$. At threshold, $\sqrt{s} \sim 2m_W$, the cross section of this process is very sensitive to m_W , providing a natural method for the measurement of this parameter. At centre-of-mass energies above the W^+W^- production threshold, m_W can be determined from the peak of the invariant mass distribution of its decay products. Both methods are very complementary : while the former requires an accurate theoretical prediction of the W^+W^- production cross section as a function of m_W and a precise determination of the collider luminosity, the latter mostly relies on a good resolution in the reconstruction of the hadronic invariant mass, and a precise control of the detector calibration.

Both methods have been used at LEP. With only about 40 pb^{-1} collected by the four LEP experiments at $\sqrt{s} \sim 161.3 \text{ GeV}$ and given the low cross section at threshold, the former is limited by a significant statistical uncertainty of about 200 MeV. The final state reconstruction method exploited the full LEP2 dataset, about 2.6 fb^{-1} collected between $\sqrt{s} \sim 161.3 \text{ GeV}$ and 206 GeV, and achieved a total uncertainty of 33 MeV. While this measurement used both the $W^+W^- \rightarrow \ell\nu qq$ and $W^+W^- \rightarrow qq qq$ channels, the fully hadronic channel is limited by uncertainties in the modeling of hadronization and interactions between the decaying W bosons, and the semi-leptonic final state dominates the precision of the final result.

Accounting for results from the CDF and D0 experiments at the TeVatron, and from ATLAS at the LHC, the present world-average value of m_W has an uncertainty estimated between 12 and 13 MeV. The uncertainty is expected to fall below 10 MeV when including final LHC measurement results. A natural goal for CEPC is thus to reach a precision well below 5 MeV, making optimal use of W^+W^- cross section data around $\sqrt{s} \sim 161 \text{ GeV}$, and of the final state invariant mass distributions at $\sqrt{s} \sim 240 \text{ GeV}$. The achievable precision of both methods is described below.

Determination of m_W from the W^+W^- production cross section

Using the threshold scan method, a precision of 1.0 MeV can be achieved for the measurement at the CEPC. We assume that the CEPC can provide a 4-point threshold scan with 2.6 ab^{-1} integrated luminosity. The \sqrt{s} values of threshold scan runs are assumed to be 157.5, 161.5, 162.5, and 172.0 GeV. The proposed run plan is shown in Table 11.10. The list of systematic uncertainties is summarized in Table 11.11.

Table 11.10: Using threshold scan measurement method in dedicated WW threshold scan runs, The proposed 4 $e^+e^- \rightarrow W^+W^-$ threshold scan runs and their integrated luminosity.

Beam Energy (GeV)	Lumiosity (ab^{-1})	Cross section(pb)	Number of WW pairs (million)
157.5	0.5	1.3	0.6
161.5	0.2	3.9	0.8
162.5	1.3	5.0	6.5
172.0	0.5	12.2	6.1

Table 11.11: Using threshold scan measurement method in dedicated WW threshold scan runs, the expected precision in m_W measurement in CEPC detectors and the comparison with LEP experiments.

$\Delta M_W(\text{MeV})$	LEP	CEPC
$\sqrt{s}(\text{GeV})$	161	240
$\int \mathcal{L}(\text{fb}^{-1})$	3	2600
beam energy scale	13	0.4
luminosity, background, signal acceptance	10	0.5
statistics	20	0.8
total	36	1.0

Determination of m_W by kinematic reconstruction

According to LEP experience, the fully hadronic final state is limited by systematic uncertainties that are difficult to control using data. The present section therefore concentrates on the semi-leptonic final states, where one W boson decays to an electron or a muon, while the other decays hadronically. An estimate of the m_W measurement potential is presented based on $WW \rightarrow \ell\nu qq$ events ($\ell = e, \mu$), and the potential of hadronic Z boson decays to calibrate the measurement of the hadronic invariant mass is evaluated.

The W^+W^- cross section at $\sqrt{s} = 240$ GeV is about 17 pb. For an integrated luminosity of 5.6 ab^{-1} , this corresponds to a sample of about 95×10^6 W boson pairs, and 28×10^6 $WW \rightarrow \ell\nu qq$ events. For ZZ production, the cross section is about 1 pb, yielding about 5.6×10^6 Z boson pairs, and 0.53×10^6 $ZZ \rightarrow \ell\ell qq$ events. While the Z boson mass is more precisely known than m_W and the $Z \rightarrow qq$ resonance provides a useful check of the detector calibration, the sample is small compared to the $W \rightarrow qq$ one, and the presence of heavy quarks in Z boson decays has to be accounted for when deriving constraints on the hadronic response in W events.

W^+W^- event selection criteria will require the presence of one reconstructed electron or muon with energy greater than 10 GeV, and missing transverse momentum greater than 10 GeV. The invariant mass of all reconstructed final state particles should exceed 50% of the centre-of-mass energy; the hadronic system, *i.e.* the set of all particles excluding the selected lepton, is clustered into two jets and its invariant mass distribution is used to probe the W boson mass. A b -tag veto can be applied to enrich the selected samples in light-quark decays, and reduce the systematic differences between the W and Z boson samples. In the $\mu\nu qq$ channel, the efficiency of these criteria is 71.3%, as shown in Table 11.12. Corresponding selection efficiencies for $ZZ \rightarrow \mu\mu qq$ events are shown in Table 11.13. The corresponding hadronic invariant mass distributions are shown in Figure 11.16. After these selections, backgrounds are expected to be small and play a negligible role in the measurement.

Given the large expected statistics, the availability of the $e\nu qq$ channel and the good resolution in the invariant mass distribution, the statistical sensitivity of the m_W measurement is better than 1 MeV. Using the $ZZ \rightarrow \ell\ell qq$ sample alone, the detector calibration can be checked to about 6 MeV. Further calibration samples can be extracted from ra-

Table 11.12: Efficiency of the event selection criteria in the $WW \rightarrow \mu\nu qq$ channel.

Selection	Efficiency (%)	Nb. of events
$E_\mu > 10 \text{ GeV}, \cos(\theta_\mu) < 0.995$	85.4	11.9×10^6
$p_T^{\text{miss}} > 10 \text{ GeV}$	82.0	11.5×10^6
$m_{\text{vis}} > 0.5 \times \sqrt{s}$	75.6	10.6×10^6
$b\text{-tag score} < 0.5$	71.3	10.0×10^6

Table 11.13: Efficiency of the event selection criteria in the $ZZ \rightarrow \mu\mu qq$ channel.

Selection	Efficiency (%)	Nb. of events
$E_\mu > 10 \text{ GeV}, \cos(\theta_\mu) < 0.995$		
$m_{\text{vis}} > 0.8 \times \sqrt{s}$		
$b\text{-tag score} < 0.5$		

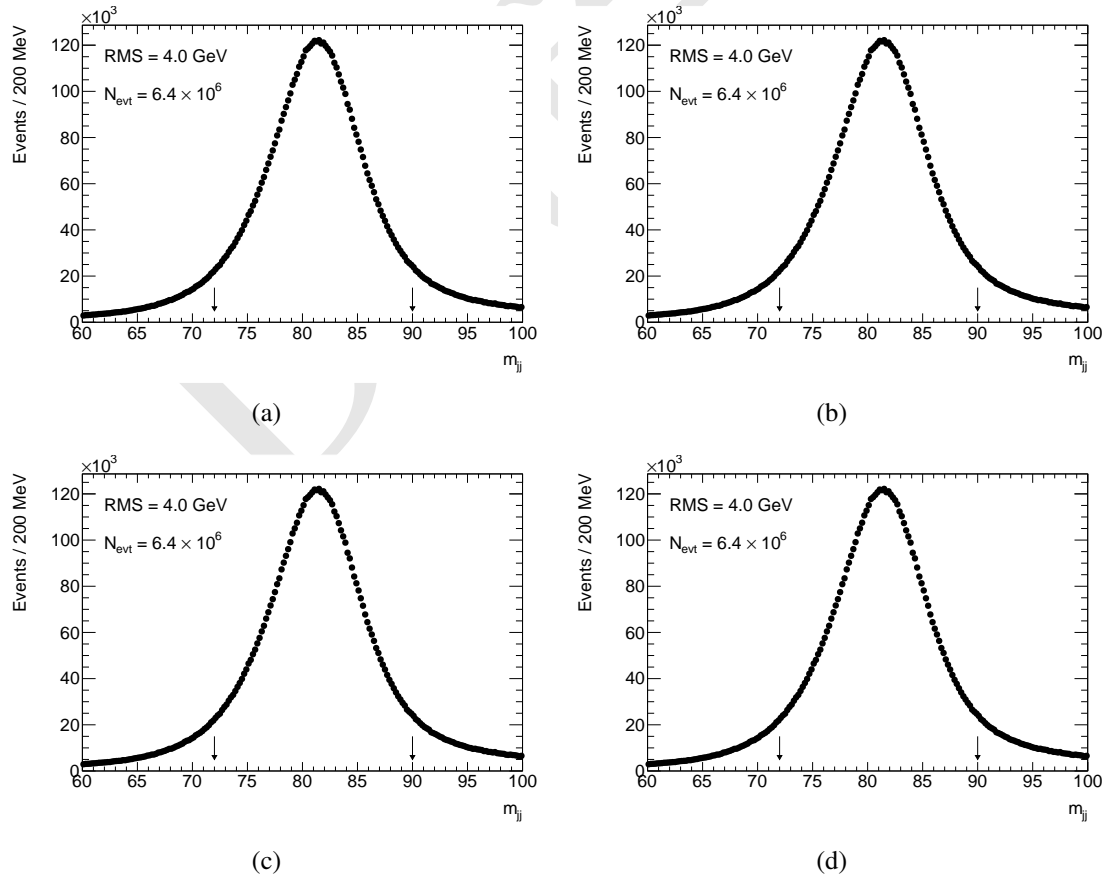

Figure 11.16: Dijet invariant mass distributions for $WW \rightarrow \mu\nu qq$ events, without (a) and with (b) a b -jet veto cut, and for $ZZ \rightarrow \mu\mu qq$ events, without (c) and with (d) a b -jet veto cut. The numbers of events and RMS of the distributions are quoted for the interval indicated by the arrows.

diative return events ($e^+e^- \rightarrow Z\gamma$). In addition, short periodic runs at $\sqrt{s} = 91.2$ GeV will be required for general detector alignment, monitoring and calibrations; these runs will provide copious samples of hadronic Z boson decays that will further constrain the hadronic calibration. Combining all information, the statistical precision of the calibration samples will match that of the W boson decays.

The statistical sensitivity can be further enhanced using kinematics fits, constraining the reconstructed lepton and jet momenta to match the known center of mass energy ($\sum_i E_i = \sqrt{s}$) and total event momentum ($\sum_i \vec{p}_i = \vec{0}$). This method was routinely used at LEP, gaining a factor of about 3 in the statistical precision, at the expense of an explicit dependence of the measurement on the beam energy. Given the expected statistical precision at CEPC, this refinement seems unnecessary here. In these conditions, the beam energy calibration, and initial state radiation are expected to contribute less than 1 MeV to the measurement uncertainty. Further significant sources of systematic uncertainty include the lepton momentum scale, which can be reduced using Z boson decays as discussed above, and the modelling of hadronization. The latter can be strongly reduced using measurements of rates and distributions of identified particles, in both Z and W boson decays.

The primary sources of uncertainty are summarized in Table 11.14, comparing LEP and CEPC. A total uncertainty at the level of 3 MeV seems reachable.

Table 11.14: Dominant sources of systematic uncertainty in the measurement of m_W using direct reconstruction, as achieved at LEP, and expected at CEPC.

Collider	LEP	CEPC
\sqrt{s} (GeV)	180–203	240
$\int \mathcal{L}$	2.6 fb ⁻¹	5.6 ab ⁻¹
Channels	$\ell\nu qq, qq\bar{q}\bar{q}$	$\ell\nu qq$
Sources of uncertainty (MeV)		
Statistics	25	1.0
Beam energy	9	1.0
Hadronization	13	1.5
Radiative corrections	8	1.0
Detector effects	10	1.5
Total	33	3.0

11.2.3 Oblique Parameter

Using the estimated experimental capabilities of CEPC, we carry out a fit to determine the sensitivity of CEPC to the oblique electroweak parameters S and T [17, 18]. We omit the parameter U that is often included in fits as it arises from a dimension-8 operator in theories with a weakly coupled Higgs boson [19], and so is expected to be much smaller than S and T which arise at dimension 6. In the electroweak fit we treat the following five

Obs.	Value	Exp. Uncertainty	Th. Uncertainty
$\alpha_s(M_Z^2)$	0.1185	1.0×10^{-4} [21]	1.5×10^{-4}
$\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$	276.5×10^{-4}	4.7×10^{-5} [22]	–
m_Z [GeV]	91.1875	0.0005	–
m_t [GeV] (pole)	173.34	0.6 [23]	0.25 [24]

$R_b \equiv \Gamma_b/\Gamma_{\text{had}}$	0.2158459 [28]	4.3×10^{-5}	7×10^{-5}
$R_\ell \equiv \Gamma_{\text{had}}/\Gamma_\ell$	20.751285 [28]	2.1×10^{-3}	1.5×10^{-3}
$\Gamma_{Z \rightarrow \text{inv}}$ [GeV]	0.167177 [28]	8.4×10^{-5}	–

Table 11.15: Inputs to the CEPC fit. Numbers in bold are expected experimental uncertainties from CEPC measurements. Other entries reflect anticipated uncertainties at the time of CEPC operation. The numbers in the “Value” column for the first five parameters are current measurements; those below the horizontal line give the Standard Model calculated value as a function of the five parameters. Theory uncertainties are future projections assuming complete 3-loop calculations, based on estimates in Refs. [25, 26, 29, 30].

well-measured observables as parameters, from which the Standard Model prediction for all of the other observables may be computed:

$$\alpha_s(m_Z^2), \Delta\alpha_{\text{had}}^{(5)}(m_Z^2), m_Z, m_t, m_h. \quad (11.18)$$

Of these parameters, CEPC is expected to significantly improve our knowledge of m_Z . The primary power of CEPC is in improving the precision of measurements of other observables, including m_W and $\sin^2 \theta_{\text{eff}}^\ell$, which may be derived from these parameters. Readers interested in more background information may find a thorough and up-to-date review of the status of electroweak precision in Ref. [20].

The inputs to the fit are listed in Table 11.15. Notice that we have performed the fit directly using forward-backward asymmetry parameters $A_{\text{FB}}^{0,f}$ as inputs, rather than the derived quantities $\sin^2 \theta_{\text{eff}}^f$ that were used in earlier work [31, 32]. The forward-backward asymmetries more directly reflect the experimental measurements; on the other hand, theoretical predictions are often expressed in terms of the effective weak mixing angles [26, 27]. They are related through the asymmetry parameters A_f :

$$A_f = \frac{1 - 4|Q_f| \sin^2 \theta_{\text{eff}}^f}{1 - 4|Q_f| \sin^2 \theta_{\text{eff}}^f + 8|Q_f|^2 \sin^4 \theta_{\text{eff}}^f}, \quad (11.19)$$

$$A_{\text{FB}}^{0,f} = \frac{3}{4} A_e A_f. \quad (11.20)$$

There is an extensive literature on the computation of the S and T dependence of observables (e.g. [17, 18, 33]); a convenient tabulation of the results may be found in Appendix A of [34]. Assembling these results, we obtain a prediction of the observables in terms of the five input parameters, S , and T . In the fit we compute a profile likelihood, floating the five parameters to obtain the maximum likelihood for given S and T .

The fit is performed following [31] (which in turn relied on [35–37]): in constructing a likelihood we treat experimental uncertainties as Gaussian but theory uncertainties as a flat prior, leading to an effective χ^2 function

$$\chi_{\text{mod}}^2 = \sum_j \left[-2 \log \left(\text{erf} \left(\frac{M_j - O_j + \delta_j}{\sqrt{2}\sigma_j} \right) - \text{erf} \left(\frac{M_j - O_j - \delta_j}{\sqrt{2}\sigma_j} \right) \right) - 2 \log \left(\sqrt{2\pi}\sigma_j \right) \right], \quad (11.21)$$

with M_j the measured value, O_j the prediction for the observable, σ_j the experimental uncertainty, and δ_j the theory uncertainty.

Our estimates of theory uncertainties assume that full three-loop computations of the parametric dependence of observables in the Standard Model will be completed. The remaining uncertainties are estimated based on [25, 26, 29, 30]. In the case of the W mass measurement, an uncertainty of 1 MeV from the computation of the near-threshold WW cross section is added in quadrature with the estimated four-loop theory uncertainty in the observable itself.

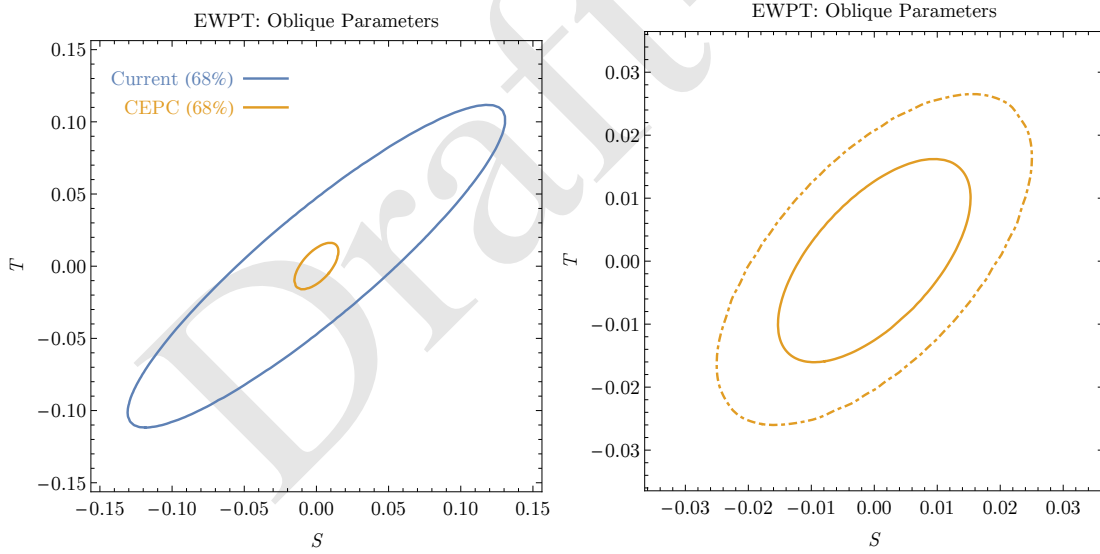

Figure 11.17: CEPC constraints on the oblique parameters S and T . Left panel: comparison of CEPC projection (orange) to current constraints (blue). Contours are 68% confidence level. Right panel: a closer look at the CEPC fit, showing 68% confidence level (solid) and 95% confidence level (dashed).

The results of the fit are depicted in Fig. 11.17. Solid contours are 68% confidence level curves, meaning $\Delta\chi_{\text{mod}}^2 = 2.30$; the dashed contour is 98% C.L. ($\Delta\chi_{\text{mod}}^2 = 6.18$). For clarity we have assumed that the measured central values will precisely agree with Standard Model predictions. In particular, the contour depicting current constraints is artificially displaced to be centered at the origin, though it accurately reflects the size of the uncertainties in current data. From the figure, we see that the results of CEPC will significantly shrink the error bars on the S and T parameters relative to currently available data.

By fixing $T = 0$ or $S = 0$, we can also obtain the projected one-parameter 68% C.L. bounds on S and T . As one-parameter fits these correspond to $\Delta\chi^2_{\text{mod}} = 1.0$. We obtain:

$$|S| < 3.6 \times 10^{-2} \text{ (current)}, \quad 7.9 \times 10^{-3} \text{ (CEPC projection)}, \quad (11.22)$$

$$|T| < 3.1 \times 10^{-2} \text{ (current)}, \quad 8.4 \times 10^{-3} \text{ (CEPC projection)}. \quad (11.23)$$

Thus CEPC will achieve about a factor of 4 additional precision on both of the electroweak oblique parameters.

CHAPTER 12

FUTURE PLANS AND R&D PROSPECTS

Since the release of the pre-CDR, the main effort of the CDR has been focusing on exploring different concepts of the detector design. In addition to a baseline detector optimized from ILD with 3T magnetic field, two alternative detectors are also proposed. One with a full-silicon tracker and another one with a drift chamber under 2T magnetic field. The baseline concept detector is used to evaluate the physics potential of the 240 GeV CEPC accelerator.

For the next TDR phase more in-depth studies will be carried out. (ADD SUMMARY OF THE REST SECTIONS...)

12.1 Tracking

12.1.1 Vertex

As the inner most layers, the vertex detector has to fulfill the most demanding requirements imposed by the physics program. To meet these requirements of single-point resolution, low material budget, fast readout, low power consumption and radiation tolerance, coherent R&D activities have to be pursued:

- Enhancement of density, radiation hardness and ultra-light module assembling.
- Explore smaller production line for TowerJazz and LAPIS in conjunction with the NpD (Nano-particle deposition) technique.
- Improve the charge collection efficiency of the TowerJazz process by N-type implant
- Improve the radiation hardness and low power design for SOI process.

- Sensor thinning for CMOS and SOI.
- Detailed designs for mechanical supports to enable cooling, cabling and power conservation.

12.1.2 Silicon tracker

Placed outside the vertex detector and after the TPC, the silicon tracker forms the complete tracking system of CEPC. The silicon tracker is designed to have low material budget and high tracking efficiency. With preliminary studies, several critical R&D items are identified for the next TDR phase:

- Alternative pixelated strip sensors with CMOS technologies;
- p^+ -on-n silicon microstrip sensors with slim-edge structure;
- Front-end electronics with low power consumption and low noise, fabricated with CMOS technologies of small feature size;
- Efficient powering with low material budget and CO_2 cooling techniques;
- Lightweight but robust support structure and related mechanics;
- Detector layout optimization, in particular in the forward region.

12.1.3 TPC

Time Projection Chambers is considered as the baseline central tracker for the CEPC tracking system. Modularized design with gas amplification and readout pad optimization have been investigated. The low power consumption electronics and ion backflow (IBF) are also considered. The future R&D consists:

- Hybrid structure TPC detector module,
- Laser calibration and alignment system.

12.1.4 Full-silicon tracker

To demonstrate a viable option for CEPC under the same detector boundary conditions of the baseline design, the TPC is replaced with a full-silicon tracker (CEPC-FST) layout. A second approach is used to fulfill the CEPC tracking volume with the ILC-SID tracker to achieve better momentum resolution. To explore the full potential of the all silicon tracker, possible improvements are:

- Optimize the layout for better performance and lower cost based on satisfy mechanics.
- Study physical performance and find out which physics processes are suitable for evaluation.

12.1.5 Drift Chamber tracker

NEED TO BE ADDED BY FRANCO ...

- TO BE ADDED...

12.2 Calorimetry

Electromagnetic calorimeter (ECAL) and hadron calorimeter (HCAL) makes the calorimeters of the CEPC detector which is use for precise energy measurements of electron, photon, tau and hadronic jets. The basic requirements for ECAL and HCAL resolution are $16\%/\sqrt{E}$ and $50\%/\sqrt{E}$ with the Particle Flow Algorithm (PFA). The main development areas are:

12.2.1 HCAL

The future plans of HCAL should include prototype design and construction based on MOST funds support.

- DDHCAL based on RPC, Test beams and performance study
- MRPC with better time resolution (about 50ps)
- AHCAL based on scintillator + SiPM, prototype design and construction, performance study

12.2.2 Dual-readout calorimeter

Concerning the dual-readout calorimeter, a 3-year R&D programme is being pursued in order to address and clarify the following issues:

- absorber material choice, current candidates are lead, brass and iron;
- machining and assembly procedure for modules of $\sim 10 \times 10 \text{ cm}^2$ cross section;
- development of a modular, projective solution for a 4π calorimeter concerning both the construction of single modules and the design and construction of a full detector;
- identification of adequate solid-state photo-sensors in order to independently optimise both Čerenkov and scintillation light detection (with respect to PDE, linearity, dynamic range and cross-talk performance);
- readout granularity (i.e. identify the optimal fibre grouping into a single readout channel);
- identification of a tailored front-end electronics, likely composed by an ASIC and an FPGA chip, in order to extract in real time both charge and time information (in principle, a time resolution of 100 ps should allow to identify the shower starting point inside the calorimeter with a precision of about 6 cm);
- particle ID performance with Particle Flow Algorithms, with and without a longitudinal segmentation;
- development and validation of full and fast simulations of both testbeam modules and an integrated 4π detector;
- assessment of the performance for the most relevant physics channels (such as W, Z, H decays).

12.3 Magnet

A detector superconducting solenoid with 3.0T central field is chosen for this CDR for feasibility reasons. It makes full cancelation to avoid disturbance to the beam with technologies in coming years. For the TDR phase, the following R&D work will be conducted:

- Further development of longer and higher I_c Aluminum based NbTi superconductor, the length longer than 100m, and I_c will larger than 15kA at 4 T background magnetic field. (For the reference, we have developed 10m long Aluminum based NbTi superconductor, the I_c 5kA at 4 T background magnetic field up to now.)
- Build a prototype to study large coil winding process and cooling method by liquid helium thermal siphon.
- Study of candidate option by using large HTS magnet and the related cooling method at 20K.

12.4 Muon system

Located within the solenoid flux return yoke, the muon system is required to identify muons with very high efficiency. Both Resistive Plate Chamber (RPC) and Micro Pattern Gas detector (MPGD) are considered in CDR. Future R&D requires detailed studies of different technologies and further optimization of baseline design parameters. Several critical R&D items have been identified, including:

- Long-lived particles optimization: Explore new physics scenario of long-lived particles and exotic decays. Optimize detector parameters and technologies.
- Layout and geometry optimization: Detailed studies on the structure of the segments and modules need to be carried out to minimise the dead area and to optimise the interface for routing, support and assembly.
- Detector optimization: Study aging effects, improve long-term reliability and stability, readout technologies.
- Detector industrialization: Improve massive and large area production procedures for all technologies.

12.5 DAQ

New technologies will emerge before the CEPC DAQ system has to be built. Attention will be made to follow and explore the ongoing improvement of the data communication and processing technologies. In particular the following areas will be addressed:

- The high speed and low latency communication technology should be the key point for data readout.
- A high efficient data flow distribution schema is another key point for data dispatching on a huge computing farm. There the data are concentrated, re-formatted, possibly zero-suppressed, assembled full event and filtered.

- Online software trigger and data compression algorithm should be study and provided by physics. But the implementation of the data processing inside online farm is DAQ scope.

12.6 Machine detector interface

Machine-Detector Interface (MDI) represents one of the most challenging topics in which both the accelerator and detector will be covered. The interaction region (IR) has to focus both electron and positron beams to small spot sizes to maximize the machine luminosity. The following R&D will be carried out during the next TDR phase:

- Interaction region layout re-design/optimization
- Background models validation with experimental data, e.g. SuperKEKB/Belle II
- Beampipe design together with SR photon protection, HOM absorber and cooling if needed
- Installation scheme that involves both LumiCal and final focusing magnets
- Prototyping R&D on LumiCal, and demonstration of alignment of desired precision with laser and optical devices.

12.7 Physics objects performance

The physics objects performance is determined by the detector geometry and reconstruction algorithms, including tracking, particle flow, and particle identification algorithms. For the TDR phase, the following items should be addressed:

- Theory/Pheno: The control of theoretical uncertainty
- Data analysis: Calibration Methods, In-situ Calibration
- Development and validation of sub-detector digitization algorithms.
- Advanced reconstruction algorithm and pattern recognition studies.
